Introduction

The search for a biological anomaly labeled as a risk factor before dental implants is limited to disease states such as diabetes, periodontitis and smoking. However, it seems in recent years cholesterol and vitamin D levels should be more systematically investigated [1]. There is also clearly a close relationship between cholesterol, and vitamin D. It is interesting to note that cholesterol and vitamin D have the same precursor, namely, 7-Dehydrocholesterol [2]. There is good cholesterol (high-density lipoprotein [HDL]) and bad cholesterol (low-density lipoprotein [LDL]) [3]. Vitamin D is one of the most important vitamins related to bone growth hormones. In addition, vitamin D also plays a role in reducing the effects of inflammation and helps improve the body’s natural immune reactions [4].

Cholesterol and Bone Metabolism

A. What is the role of LDL?: According to Luegmayr et al, 2004 elevated levels of cholesterol may lead to an imbalance in the bone-remodeling process, a reduction of bone mass by increasing the activity, and a differentiation of osteoclasts [5]. Krüger 1998 [6] demonstrated an increase in the number of osteoclasts, the inhibition of osteoblastic activity, and a decreased bone remodeling in hyperlipidemic rats. An increase of circulating levels of oxidized LDL induces alveolar bone loss and is associated with the severity of the local inflammatory response to bacteria as well as the susceptibility to periodontal disease in diabetic patients [7].

The bone releases enzymes that are involved in the oxidation of LDL. It is possible that the oxidized LDL accumulated in the bone could induce subsequent deleterious cellular effects on bone density [8]. Hyperlipidemia causes a reduction of bone density in vivo due to the inhibition of osteoblast differentiation by bioactive lipids [9]. Oxidized LDL caused an inhibition of the alkaline phosphatase activity and also mineralization, which are markers of osteoblast differentiation. In addition, it has recently been shown that oxidized LDL also induces cell death by apoptosis of osteoblastic cells [10]. Hirasawa et al. [11] 2007 confirmed that atherogenic conditions (high LDL levels) caused the death of osteoblasts. Oxidized low-density lipoprotein particles have been shown both to stimulate the proliferation and promote apoptosis of bone-forming osteoblasts [12].

Oxidized low density lipoproteins (OxLDL) are known to promote atherosclerosis, but it is only recently that OxLDL have been associated with alterations of the functions of bone-forming osteoblasts and osteoporosis. HDL3 prevent the cell death induced by OxLDL in human osteoblastic cells. Simultaneous exposure of the cells to HDL3 and OxLDL abolished the reduction of cell viability monitored by MTT activity measurement and the induction of apoptosis determined by annexin V staining indicating that HDL3 prevent the apoptosis of osteoblasts induced by OxLDL. This protection correlated with the displacement by HDL3 of OxLDL association to osteoblasts, signifying that OxLDL binding and/or internalization are/is necessary for their cytotoxic effects [13].

B. What is the role of HDL?: Various antioxidants carried by HDL may interrupt the cascade of events leading to the oxidation of LDL [14]. Another important property of HDL is its ability to inhibit cell death induced by oxidized LDL. In particular, it has been reported that HDL inhibits the apoptosis of monocyte cells by inducing cholesterol efflux and thus preventing the accumulation of cholesterol caused by the presence of oxidized LDL. HDL should be considered as a bone cell protector [15]. Brodeur et al. 2008 found that osteoblastic cells to HDL3 prior to incubation with OxLDL reduced cell death and preserved the lysosomal integrity.
This protection was correlated with an increase of a modification of OxLDL metabolism with less global uptake of OxLDL and greater selective uptake of cholesterol from OxLDL. These results strongly suggest that, as for atherosclerosis, HDL may exert beneficial actions on bone metabolism [13]. Osteoclasts depend on lipoproteins to modulate cellular cholesterol levels and this controls osteoclasts formation and survival. Removal of cholesterol in osteoclasts via high-density lipoprotein or cyclodextrin treatment dose-dependently induced apoptosis, with actin disruption, nuclear condensation and activation. Consistent with these findings, cholesterol delivery via low-density lipoprotein (LDL) significantly increased osteoclasts viability. When cholesterol was chemically delivered during differentiation with hyperlipidemia being associated with disease of the vascular system and bone, these findings provide novel insights into the selective lipoprotein and cholesterol dependency of the bone-resorbing cell [16].

### Table 1: Serum level values.

| Lipoprotein values | Men <1.6 g/L | Women <1.5 g/L |
|--------------------|--------------|----------------|
| Cholesterol total  | <2g/L        |                |
| Triglycerides      | <2g/L        |                |
| LDL cholesterol    | Men <1.6 g/L | Women <1.5 g/L |
| HDL cholesterol    | >0.35 g/L    |                |

**C. What is the Serum level of lipoprotein?** Serum level values are shown in Table 1. The result of high LDL is a reduction of bone metabolism, inhibition of phosphatase alkaline, and an increase of the fat part in the bone. The result is a lower osseointegration and slower bone growth [1]. Branemark said in 1985, during an international meeting, «When I see a yellow bone, I cancel the transplant!» At that time, it was only a clinical observation [1]. We now understand why. We have been focused on the high cholesterol risk in bone grafts for more than 10 years, and now we can explain why we had more failures in these cases [1].

A retrospective cohort study done by Federico et al. 2016 was conducted on 268 sequential patients scheduled for implant and bone augmentation surgery, patients were divided into two groups: Total serum cholesterol (TC) TC < 200 mg/dl and TC > 200 mg/dl. A 6-month post-loading follow-up was scheduled both for implants and grafts. The effect of cholesterol on early implant and grafting failure was investigated according to a logistic regression model. The Results were two hundred and twenty-seven patients fulfilled inclusion criteria; 139 had hypercholesterolemia. The 6-month post-loading overall implant failure rate was 6.25% at patient level (2.00% at implant level).

Partial or total graft infection rate was 10.2%. High TC increased by 7.48 times the odds of the grafting failure (P = 0.047; 95% CI: -0.94 to 5.92), whilst it did not modify the odds of implant failure (P = 0.749; 95% CI: 0.28 to 2.49). Federico conclusion was high total serum cholesterol levels tend to increase graft failure rates whilst it did not influence implant failures [17]. Kırzıoglu et al. [18] 2016 did experimental study on rats were randomized into the four groups: 1-group C (standard diet/periodontally healthy); 2-group Hc(high-cholesterol diet); 3-group HcP (high-cholesterol diet/periodontitis); and 4-group P (standard diet/periodontitis).

All rats were fed for 8 weeks. At 6 weeks, experimental periodontitis was induced. At the end of week 8, the rats were sacrificed. Histomorphometric and histopathologic analyses were performed. The result was significant in the HcP group a high-cholesterol diet, with or with-out periodontitis. Kırzıoglu concluded cholesterol-enriched diet could lead to an increase in periodontal inflammation and alveolar bone loss [18].

**D. Low vitamin D incidence on osseointegration and bone grafts:** The most important related compound of vitamin D is vitamin D3 (cholecalciferol) (25-hydroxyvitamin, 25OHD3). Vitamin D is a steroid hormone that is acquired via diet or synthesized in the skin from cholesterol when sun (ultraviolet light) exposure is adequate (Figure 1) [19]. Cholesterol is converted to pre-vitamin D3 and then isomerized to vitamin D3. After binding to vitamin D-binding carrier protein, vitamin D3 is transported to the liver, where it is enzymatically hydroxylated by CYP27A1, generating 25-hydroxyvitamin D3 (calcidiol, or 25OHD3) [19].

In the bone, vitamin D stimulates the activity of osteoclasts and increases the production of extracellular matrix proteins by osteoblasts. Vitamin D also stimulates intestinal calcium absorption and inhibits the synthesis and secretion of parathyroid hormone [20]. Vitamin D deficiency can result from inadequate dietary intake together with the insufficient exposure to sunlight. Vitamin D deficiency in these patients is associated with a catabolic bone turnover and its main consequence, the occurrence of osteoporotic fractures [21]. Vitamin D deficiency has also been linked to impaired fracture healing in clinical practice and in patients suffering a fracture [22]. These results support the role of the steroid hormone in controlling bone regeneration.
As osseointegration of dental implants also depends on bone regeneration, peri-implant bone formation was shown to be reduced in vitamin D deficient rats [23]. Dvorak et al. [24] 2012 indicated that vitamin D deficiency has a negative impact on cortical peri-implant bone formation in ovariectomized rats, which can be compensated by a vitamin D-rich diet. Vitamin D has also been implicated in several allergic disorders and immune system dysregulation. It has extensive immunomodulatory effects. It is now known that cells from the immune system contain all the characteristics needed to convert 25-hydroxy vitamin D to active 1,25-dihydroxyvitamin D during a bacterial infection [4].

These peptides have a broad range of actions against microorganisms, including bacteria, fungi, and viruses [25]. Frieri and Valluri, 2011 showed that there was also a positive correlation with allergy subtypes and sinus infections with low vitamin D [26]. Flynn et al. [25] 2012 showed that vitamin D levels <20 ng/mL have a significant impact on length of stay, organ dysfunction, and infection rates. Vitamin D has since been studied in several clinical trials to characterize its role in respiratory infections [27]. Vitamin D also plays a predominant role in allergy. Numerous data are published on the relationship between vitamin D and asthma and allergic patients are often deficient in vitamin D [28,29].

Table 2: Serum level values.

| Vitamin D levels | Deficiency<10 ng/mL | Insufficiency | 10-30 ng/mL | Optimal | >30 ng/mL |
|------------------|---------------------|---------------|-------------|---------|----------|

E. What is the Serum level of vitamin D?: Serum level values are shown in Table 2. Daily needs of vitamin D are 4000 IU, and the lack of sufficient vitamin D in one’s diet is very common: An estimated 1 billion people worldwide are vitamin D deficient [21]. Maier et al. [30] 2013 asked: Is there an epidemic vitamin D deficiency in German orthopedic patients? Among preoperative orthopedic patients, he found that 85% were insufficient and 60% were deficient. Sabetta et al. [31] 2010 conducted a prospective cohort study showing that serum 25(OH)D concentrations of 38 ng/mL or greater were associated with a 2-fold decrease in the number of upper respiratory infections. Vitamin D deficiency has been also implicated in various diseases such as diabetes, high blood pressure, cardiovascular diseases, and many cancers [20]. Vitamin D serum level plays a predominant role in bone metabolism, sensibility to infections, and many allergy symptoms [29]. Vitamin D may also affect the body’s susceptibility and response to infectious organisms, a major trigger of wheezing at a young age [28].

F. The supplementation of vitamin D in a daily diet also decreases the LDL cholesterol: The link between osteoporosis and the metabolic syndrome could influence the therapeutic approach in both disorders and vitamin D. Supplementation may play an important role in prevention of these severe conditions [32]. Dvorak et al. [33] 2012 did a study on ovariectomized rats and he found in his results vitamin D deficiency has a negative impact on cortical peri-implant bone formation in ovariectomized rats, which can be compensated by vitamin D supplementation. We suggest exploring vitamin D serum level and LDL Cholesterol systematically in patients who are diabetic, allergic, with hypertension, and previously in a difficult case of implants and/or bone grafting. This exploration is largely indicated in the cases of a failure of bone graft or implant placement [1].

Conclusion

The assessment of the total serum cholesterol levels and vitamin D status, it is indicated and necessary for dental implants or bone grafts patient.
