In this work we present results of the magnetic properties characterization of sediment samples from a brownfield site that is generating methane biogas in São Paulo–Brazil. We applied interpretation procedures (frequency dependent susceptibility and time-dependent Isothermal Remanent Magnetization) appropriate to study the ultrafine magnetic fraction response of the samples. The higher content of superparamagnetic (SP) particles correlates well with the detected biogas pockets, suggesting that the methanogens activity produces these ultrafine particles, different from the magnetic particles at other depth levels. We propose the use of two simple measurement and interpretation techniques to identify such magnetic particles fingerprints. The results presented here support the use of environmental magnetism techniques to investigate biogeochemical processes of anaerobic microbial activity.

Keywords: direct inter species electron transfer (DIET), magnetic nanoparticles, superparamagnetic particles, methane, brownfield, organic rich sediments

INTRODUCTION

Organic matter buried in anaerobic environments, (e.g. landfills or organic-rich sediments) is oxidized through a series of biogeochemical processes producing methane and carbon dioxide as major products (Christensen, 2010). The well-known electron sources for carbon dioxide reduction to methane are H2 (Sieber et al., 2012) or other dissolved carriers (Bryant et al., 1967; Stams and Plugge, 2009). Recent findings however have shown that Methanosaeta and Methanosarcina species can directly accept electrons from Geobacter as donors via direct interspecies electron transfer (DIET), in this process reducing carbon dioxide to methane (Chen et al., 2014a; Rotaru et al., 2014a; Chen et al., 2014b; Rotaru et al., 2014b; Wang et al., 2016; Xiao et al., 2018). Possible mechanisms of electron transfer in DIET-based syntrophy seem to be through electrified paths formed by pil-like appendages with conductive minerals or outer cell electrical connectors of adjacent partners (Lovley, 2017). DIET connection of Methanosaeta with Geobacter species has been recognized (Summers et al., 2010; Lovley, 2011; Shrestha et al., 2013a; Shrestha et al., 2013b) and assumed as a major player in global methane budget (Rotaru et al., 2014b). Methane production based on DIET can be stimulated by introducing conductive particulates (Martins et al., 2018), such as biochar (Chen et al., 2014a; Xiao et al., 2019); carbon cloth (Li et al., 2018) and magnetite nanoparticles (Kato et al., 2012; Zhang and Lu, 2016; Xiao et al., 2018) suggesting the importance of conductive particulate to shuttle interspecies electron-transport.
In principle, syntrophic DIET associations can sustain methanogenesis in H₂ depleted environments (or other dissolved carriers) by directly coupling iron-reducing bacteria with methanogens. It is accepted that the partnership between Geobacter and Methanosarcina can competitively exclude acetoclastic methanogens like Methanotrithrix in the absence of dissolved electron carrier (Rotaru et al., 2018). Paddy soil incubation of ferrihydrite indicates that methanogenesis is initially suppressed as magnetite grains are produced and Geobacter proliferates, and then enhanced as DIET develops using the magnetite network for interspecies electrical connections (Liu et al., 2015). Other species such as Syntrophomonas has been proposed as candidates for DIET with Methanosetae suggesting that many microorganisms are capable of DIET processes (Zhao et al., 2018).

Magnetite production and alteration then may develop a major role in DIET syntrophy, either in stages in which Fe(III) reduction are catalyzed by iron-reducing bacteria as used to convey electron-transfer between interspecies partners. Iron speciation by dissimilatory iron-reducing bacteria is widespread in waterlogged soils (Lovley et al., 1987; Maher and Taylor 1988) and their importance for iron cycling in such environments makes them a key potential source of ultra-fine soil magnetite (Roberts, 2015). A proxy characterizing concentration and magnetite properties (grain size and mineral type, for example) may be useful to recognize a biogeochemical process active in modern environments or recorded in continuous coring of sedimentary sequences. A diversity of iron-reducing microorganisms can convert poorly crystalline Fe(III) oxy/hydroxides to extracellular magnetite while using Fe(III) as an electron acceptor for the oxidation of organic compounds (Lovley et al., 2004). The Fe (III) reducing bacteria Geothrix has been shown to produce magnetite at brownfield sites (Klügel et al., 2013) and it has been suggested the Geothrix can act in syntrophy with methanogens though not necessarily via a DIET mechanism (Sutcliffe et al., 2018). Common Fe(III) minerals in soils and sediments are hematite (α-Fe₂O₃), ferrihydrite (5Fe₂O₃.9H₂O) or oxyhydroxides goethite (α-FeOOH), lepidocrocite (γ-FeOOH). The reduction of Fe(III) minerals to produce magnetite (Fe₃O₄) is energetically favorable (−0.01 eV), adding 1 Bohr magneton (9.27×10⁻²⁴ Am²) to the crystalline frame, which represents a magnetization upgrade of about 25% (Liu et al., 2012).

Depending on culture conditions and bacterial forms (Vali et al, 2004), the respiration of iron-reducing bacteria based on solid Fe(III) mineral phases produces extracellular magnetite crystals (Lovley et al., 1987; Lovley, 1991; Coker et al., 2008) of ultrafine grains with diameters between 10 and 50 nm. The extracellular crystallization process results in particles lacking characteristic morphology but usually with superparamagnetic (SP) properties at room temperature (Moskovitz et al., 1993). The superparamagnetic response is observed when single-domain, ferromagnetic minerals are below a critical blocking volume, unable to sustain permanent magnetization at room temperature. Incubation of metal-reducing bacteria with Fe(III) oxyhydroxides have produced magnetite nanoparticles with diameters between 10 and 15 nm for bacterium Geobacter sulfurreducens (Byrne et al., 2015) and between 26 nm and 38 nm for bacterium Shewanella (Lee et al., 2008). In many environments the magnetic properties associated to ultrafine magnetite particles must be isolated in order to better understand the superparamagnetic signature associated to iron-reducing bacteria and their role in DIET syntrophy.

In this paper we study a trapped gas pocket formed in Quaternary organic sediments, by tracking specific mineral changes that can be associated to biogeochemical processes. We focus our analysis on changes regarding the magnetic carrier mineralogy analyzing the frequency dependent susceptibility and time-dependent Isothermal Remanent Magnetization (IRM) to detect subtle physical and compositional variations that could be indicative of a DIET process. In addition to classic techniques used in environmental magnetism (thermomagnetic and hysteresis curves) we apply specific procedures to characterize the SP mineral content in terms of volume variations and concentration estimates along a cored section that intercepts a methane pocket trapped within organic-rich sediments. We recognize an association between iron-reducing bacteria and occurrence of SP minerals at a region were iron-reduction is developed and methane accumulation observed, possibly according to a DIET scheme.

MATERIALS AND METHODS

Research Site

The studied site is situated at a flood plain of the Tietê River, in São Paulo - SP, Brazil. The area contains a series of anthropogenic deposits (~4 m) that overlies Quaternary fluvial sediments (~6 m) and Neogene sandstones. The entire site was formerly used as a large drying pool for dredged sediments when a nearby channel was opened. The sediments settled in the pool kept under anoxic conditions the organic-rich sediments of the fluvial plain inducing methanogenic processes and methane trapping within sandy lenses at different depths of the section. Two main methane pockets were sampled along three multilevel monitoring wells, each one with 15 gas and water sampling ports 0.6 m spaced down to 8.6 m in the Quaternary section (Mendonça et al., 2015a). Continuous samples of direct-push coring were analyzed for total content of organic carbon and grain size laser diffraction (Mendonça et al., 2015a). The trapped pockets of biogas were identified within a thick (approximately 6 m) layer of organic-rich sediments, with organic carbon up to 40% in weight. The pockets of methane were confirmed by direct gas sampling from the multilevel monitoring wells (Figure 1). The shallower accumulation (top at ~2.5 m) has pressure equilibrated to the atmosphere, while the deeper gas reservoir (depth ~6 m) is overpressured to about 0.4–0.5 kPa above the atmosphere. Gas composition in both reservoirs is enriched in CH₄, about 37–45% of CO₂ to 55–63% CH₄, with traces of H₂S (~30 ppm). The piezometric surface is relatively flat, with a hydraulic gradient of 0.00282 towards the river.
channel. High permeability (12–62 cm day$^{-1}$) of the surface anthropogenic layer does not work as an efficient sealing unit for gas pockets volumes reaching the vadose zone but it facilitates water recharge and removal of gas in this zone as the water infiltrates. A monthly based ERT (Earth Resistivity Tomography) imaging recognized one episode with methane release and paths for water infiltration during rainy periods (Mendonça et al., 2015b).

Sediments recovered from groundwater sampled from the multi-wells underwent microbial analysis. Groundwater sampled from the multi-wells underwent microbial analysis. Procedures for microbial DNA extractions, bacterial and archaeal pyrosequencing, and sequence analysis are described in Mendonça et al. (2015b). It was found that the methane-producing archaea *Methanosaeta* are ubiquitous in the environment and probably generates the methane and carbon dioxide gas pockets trapped beneath impervious layers (Figure 1). The distribution of methanogens is well correlated with the methane pockets and higher levels of acetate. *Methanosaeta* species have high affinity for acetate (Lee et al., 2014) and are ubiquitous in many natural environments. *Methanosaeta* species are also capable of direct interspecies electron accepting from some *Geobacter* species for the reduction of carbon dioxide to methane (Rotaru et al., 2014b). Based on these findings we undertook a sampling regime of the recovered cores for magnetic properties characterization to identify if there is a relationship between methane production within gas pockets and the production of biogenic magnetic minerals in soils at the same horizons.

**Magnetic Properties Characterization**

Magnetic properties of soils and rocks are strongly dependent upon magnetic carrier grain size, which are classified as multi domain (MD), stable single domain (SSD), (e.g. up to 50 nm for magnetite), pseudo single domain (PSD) or “vortex” structure. Magnetic particles formed by dissimilatory iron-reducing bacteria are typically ultrafine, as such generating mineral carriers with superparamagnetic properties, (e.g. ultrafine magnetite or greigite) from reducing Fe(III) minerals from background geological media. To characterize the magnetic properties within and in the vicinity of the methane pockets 21 sediment samples from direct pushing coring (every 0.5 m, from 0.5 to 10.5 m deep) were analysed with focus on their superparamagnetic content, by using frequency dependent susceptibility (FDS) and superparamagnetic concentration and dipole moment (SPCDM) analysis.

**Thermomagnetic Curve**

In this analysis, magnetic susceptibility changes as a function of temperature are recorded. The high temperature protocol consists of measurements during the heating stage, from room temperature to approximately 700 °C and then repeating measurements while the sample cools to room temperature. High temperature curves are useful to identify changes of mineral phase that take place at specific temperatures, (e.g. Curie temperature $T_C$ or Néel temperature $T_N$). $T_C$ marks the sudden loss of magnetization when a ferri- or ferro-magnetic mineral becomes paramagnetic in temperatures $T > T_C$. For magnetite, $T_C \sim 580$ °C. $T_N$ is the analogous of the Curie temperature in antiferromagnetic minerals such as hematite ($T_N \sim 675$ °C), where the mineral becomes paramagnetic at temperatures $T > T_N$ (Dunlop and Özdemir, 2001).

Thermomagnetic curves can also show magnetic carrier size effect, such as the Hopkinson peak (sudden increase of susceptibility temperature until a peak reached before $T_C$). Özdemir and Dunlop (2014) reported a systematic trend of the Hopkinson’s peak height with magnetic grain size for natural magnetite samples. Also recognizable is mineral phase transformations as the sample is heated and cooled. In this case, the heating and cooling curves are distinguishable from one another and are said to be irreversible, revealing mineralogical transformations caused by dehydration or change in the sample redox state.
The measurements presented in this work were taken with Kappabridge KLY-4S at USPMAG (University of São Paulo), at the heating rate of 0.2 °C/s under inert Ar atmosphere.

**Magnetic Hysteresis**

Hysteresis cycles are designed to observe the ability of a ferromagnetic material to acquire permanent magnetization under an external magnetic field. This feature is usually investigated by first applying a strong field magnetic (H) so that the magnetization (M) is saturated. As H is then decreased to zero, M does not fall to the origin. If the field increases in the opposite direction, M gradually falls to zero to then reverse again as the saturation magnetization is reached. Repeated cycling of H traces out the hysteresis loop.

The standard hysteresis parameters Mr, Ms, Hc, and Hcr (where Mr is the saturation remanence, Ms is the saturation magnetization, Hc is the coercive force, and Hcr is the coercivity of remanence) represent the bulk magnetic properties of the sample and are often used to characterize geological samples. Low coercivity materials will produce hysteresis loops of rectangular shape and mixtures of minerals with different coercivities may produce constricted hysteresis loops that are narrow in the middle section but wider above and below this region (waisted) (Tauxe et al., 1996, 2002).

The analysis of hysteresis loops at different temperatures may reveal changes in the magnetic domain state for the magnetic minerals. Magnetic grains below a certain particle size, for example, do not preserve magnetic remanence above a critical transition parameter (Tauxe et al., 1996, 2002).

Repeated cycling of H traces out the hysteresis loop. For example, an assemblage of noninteracting single domain magnetic grains below a certain particle size, for example, do not preserve magnetic remanence above a critical transition parameter (Tauxe et al., 1996, 2002).

The standard hysteresis parameters Mr, Ms, Hc, and Hcr (where Mr is the saturation remanence, Ms is the saturation magnetization, Hc is the coercive force, and Hcr is the coercivity of remanence) represent the bulk magnetic properties of the sample and are often used to characterize geological samples. Low coercivity materials will produce hysteresis loops of rectangular shape and mixtures of minerals with different coercivities may produce constricted hysteresis loops that are narrow in the middle section but wider above and below this region (waisted) (Tauxe et al., 1996, 2002).

The analysis of hysteresis loops at different temperatures may reveal changes in the magnetic domain state for the magnetic minerals. Magnetic grains below a certain particle size, for example, do not preserve magnetic remanence above a critical temperature, when the superparamagnetic condition is activated (Dunlop and Özdemir, 2001).

We used the Physical Properties Measurement System (PPMS) Quantum Design using a vibrating sample magnetometry (VSM) to record hysteresis loops at 300, 25, 10 and 5 K and maximum external field of approximately 5 × 10⁴ Oe.

**First-Order Reversal Curves (FORC)**

FORC diagrams (Pike et al., 1999; Roberts et al., 2000) provide further magnetic minerals and domain states characterization and the extent of magnetostatic interactions. FORC measurements start by saturating a sample in a strong positive field Hr, followed by changing the field to a negative field Hr and then sweeping it back to Hr. The difference between successive FORCs arises from irreversible magnetization changes that occur between successive reversal fields. FORCs distributions are interpreted in terms of the coercivity distribution and the interaction field distribution.

For example, an assemblage of noninteracting single domain particles produces closed concentric contours with negligible vertical spread of the FORC distribution, in contrast with the closed concentric contours with high vertical spread produced by interacting single domain particles. The superparamagnetic behavior is dominant in the FORC distribution when the measurement time is comparable to the relaxation times of particles near the SP-SSD threshold size (Pike et al., 2001). Multidomain particles produce a different feature in the FORC diagram, where the magnetic interactions among domain walls produce asymmetric contours, which make it straightforward to discriminate these particles.

**Frequency Dependent Susceptibility (FDS)**

FDS aims to quantify the SP-SSD response in terms of grain size variation able to explain the dependence of the magnetic susceptibility with grain size fining from a reference SSD characteristic volume. This formulation is based on the Debye relaxation model (Ustra et al., 2018) by considering measurements with three-frequency susceptibility meters usually employed to characterize superparamagnetic contents in soil and rock magnetism. According to this model, the in-phase (or real) magnetic susceptibility $\chi_r(f)$ for an assemblage of uniform magnetic carrier is $\chi_r = \chi_0 + \Delta \chi \frac{1}{1+i(2\pi f/\tau)}$, where $\chi_0$ is the FDS high-frequency limit, $\Delta \chi = \chi_i - \chi_0$ with $\chi_i$ as its corresponding low-frequency limit and $\tau$ is relaxation time constant. For measurements with a set of at least three frequencies $f_i$ (e.g. 976, 3,904 and 15,616 Hz as for the MKF1-FA Kappabridge susceptibility meter) the FDS data allow solving for unknown parameters ($\chi_0, \Delta \chi, \tau$) according to a constrained, non-linear data-fitting procedure (Ustra et al., 2019). Once estimated, such model parameters are used to determine the transition parameter $F_i = \chi_i/\chi_0 = v/v_c$, that relates the mean volume $v$ for the particle assemblage with respect to a characteristic volume $v_c = \frac{2b}{\mu_0 Hc M_r}$.

Standing for the respective mineral grains in the SP-SSD transition, in which $M_r$ is the sample saturation magnetization [Am⁻¹], $k_B$ 1.38 × 10⁻²³ [JK⁻¹] is the Boltzmann constant and $T$ [K] is the temperature $H_K$ [Am⁻¹]is the sample macroscopic coercivity and $\mu_0 = 4\pi \times 10^{-7}$ [Hm⁻¹] is the free space permeability. The quantity $F_i = \chi_i/\chi_0 = v/v_c$ can be regarded as a fining proxy since it expresses how much the particles go finer having as reference the characteristic volume for the grain. As discussed by Ustra et al. (2019) the determination of volume $v$ according to the Neel’s model $v = v_0 \ln(\tau/\tau_0)$ is inaccurate using inferences for $\tau$ from data sets with three-frequencies only. Characteristic time $\tau_0$ is a time-factor varying from 10⁻¹² to 10⁻⁸ s (Dormann et al., 1996; Worm 1999). We use the MATLAB program FDS_inv.m (Ustra et al., 2019) to invert the three-frequency dataset acquired with Kappabridge MK1 at LabCore (University of São Paulo).

**Superparamagnetic Concentration and Dipole Moment (SPCDM)**

The SPCDM procedure developed by Leite et al. (2018) is based on Neel’s model for superparamagnetism for which sample magnetization $M(B, T)$ is dependent of the external applied field $B$ and temperature $M(B, T) = M_S L \left( \frac{\mu B}{k_B T} \right)$ in which $\mu$ is the mean moment of dipole [Am²] of the magnetic carrier composing the sample; $B$ is the external magnetic field applied to the sample, $L$ is the Lagrange function such that $L(a) = \coth(a) - 1/a$. The magnetization is such that $M_S = \eta \mu$, the term $\eta$ [m³] expressing the concentration (number of particles per volume) of the magnetic carriers. For a sample with density $\rho$ [kgm⁻³], the mass concentration of the magnetic
carriers is obtained by $\eta/\rho$. The moment of dipole of the particle is such that $\mu = \nu \sigma_S$ where $\sigma_S$ is the magnetization saturation for the magnetic carrier. The SPCDM procedure isolates the superparamagnetic contribution $M(B_i, T)$ by applying a set of external fields $B_i (i = 1 : 17)$ $B_i$ ranging from 5 to 340 mT, by using a precise MicroMag3900 magnetometer, at USPMAG (University of São Paulo). These magnetization values provide unknown parameters ($M_S, \mu$) from which estimates about particle concentration ($\eta = M_S/\mu$) and particle volume ($\nu = \mu/\sigma_S$) can be achieved. For volume estimates, the magnetization of pure magnetite can be assumed in most cases. In summary, the SPCDM provides saturation magnetization ($M_S$), the particle moment of dipole $\mu$ and, from these, particle concentration $\eta$ [m$^{-3}$] and grain volume $\nu$, if saturation magnetization $\sigma_S$ for mineral carrier is known.

RESULTS AND DISCUSSION

The thermomagnetic measurements presented in Figure 2 served as a preliminary analysis to identify the magnetic mineralogy diversity at the site. All heating curves captured the magnetic susceptibility increase above 250–300 °C, indicating transformations of iron (hydr)oxides under a reducing atmosphere (Hanesch et al., 2006). While heating, the magnetic susceptibility increases with temperature to around 400–580 °C, followed by a significant loss of magnetization, indicating the occurrence of magnetite. The magnetic susceptibility increase indicates transformations of paramagnetic or clay minerals into magnetite (Roberts, 2015).

It is possible that ferrihydrite is being converted to magnetite, a common product of bacterial Fe(III) hydroxide reduction. The precipitation of magnetite in ferrihydrite reduction by dissimilatory Fe(III)-reducing microorganisms has been reported by several studies, (e.g. Lovley et al., 1987; Vali et al., 2004; Coker et al., 2008; Zhuang et al., 2015).

Even though magnetite is visible in the irreversible thermomagnetic curves, the presence of magnetite in the soils, prior the transformation of ferrihydrite into magnetite is verified in the FORC diagrams. Figure 3A) shows a clear SD-like behavior on 2.5 m (anthropogenic sediments) with small asymmetrical spread (higher towards the positive area) in the $Bu$ axis, peaking around zero, indicating little to no magnetic interaction. The coercivity distribution peak in $Bc$ is around 20 mT, evidence of magnetite, in accordance to the thermomagnetic curves. Figure 3B) shows the FORC diagram from the sample collected at 6 m (Quaternary sediments). A maximum coercivity peak close to the origin at around 5mT indicates a prevalent reversible component of magnetization (Sagnotti and Winkler, 2012), with open contours diverging asymmetrically on the $Bu$ axis, showing resemblance to SP dominated population of
grains (Roberts et al., 2014). The FORC also shows strong interaction fields (Bu) spreading until coercivities of 40 mT.

Samples collected at depths of 2.5 and 8 m were submitted to hysteresis cycles taken at distinct temperatures (Figures 4A–C, respectively). Below room temperature, the magnetization processes are irreversible and produces the ferromagnetic hysteresis loop. However, Figures 4A,B (2.5 m) and (8.0 m) capture the magnetic carrier’s inabilities to sustain magnetization at room temperature (300 K, also shown as insets graphs), producing a superparamagnetic response of the sigmoidal shape of a ferromagnetic response, but losing the loop.

With evidence of SP-SSD particles in the magnetic particles assemblages, quantitative interpretation techniques based on the SP-SSD magnetic response were applied (see Supplementary material for individual FDS and SPCDM analysis). Figure 5 shows the depth profiles of the measured magnetic susceptibility, $F^{-1}$, obtained from FDS measurements and superparamagnetic particles concentration, $\eta$. Magnetic susceptibility measurements (Figure 5A) show that the shallower portion of the soil is more magnetic and MS decreases with depth. The high MS in the uppermost 2.5 m is attributed to the unsaturated sediments magnetic properties. The maximum value of magnetic susceptibility is observed at 2.5 m, a known zone of gas pocket. Even though magnetic susceptibility decreases with depth, around 6.5 m it increases again, at a depth coincident with the second gas pocket zone. The parameter $F^{-1}$

---

**FIGURE 3** | FORC distribution of sample collected at (A) 2.5 m (anthropogenic deposit sediments) and (B) 6.0 m (Quaternary sediments). At 2.5 m the contours present small asymmetrical spread in the Bu axis, with a peak around zero, indicating single domain behavior with little to no magnetic interaction. The coercivity distribution peak in $B_c$ around 20 mT is evidence of magnetite. At 6.0 m, open contours diverging asymmetrically on the Bu axis indicate dominance of SP population of grains.
(Figure 5B), an estimation of the SP-SSD size variations, reveals that magnetic particles present a more significant frequency effect at 4.5 and 6.5 m. We interpret that magnetic carriers size variations in the SP-SSD threshold are more significant at these two depths, which is at the boundary of the second gas pocket zone. The superparamagnetic particles concentration (SP concentration) profile (Figure 5C) shows two peaks, which agree with the gas pockets depths (0.5–2.5, 5–6 and 10.5 m).
The high MS values are not always in agreement with high SP particles shown by $\eta$, demonstrating that increasing content of SP ferrimagnetic particles alone cannot account for the variations of magnetic susceptibility of all samples. This apparent contradiction results from the limitations of both the FDS and the SPCDM methods. The FDS method captures a relaxation from magnetic particles within the SP-SSD threshold, in the 976–15,616 Hz AC field frequency range. On the other hand, the SPCDM captures faster relaxations, which are produced by finer particles (higher relaxation frequencies).

In this study, both methods were complementary, delimiting a zone of increasing the abundance SP-SSD particles (high $F_{t}^{-1}$ and low $\eta$) and a zone of mostly SP particles (low $F_{t}^{-1}$ and high $\eta$).

In the unsaturated zone, from 0.5 to 2.5 m, we believe that superparamagnetic particles are formed in a different process that will not be discussed in this work, where the grain size is not affected. The linear correlation between MS and $\eta$ shown in Figure 6 evidence that $\eta$ follows the same pattern as
magnetic susceptibility within this anthropogenic layer, suggesting the magnetic response of this portion is dominated by the superparamagnetic particles. \( F^{-1} \) closer to one supports the interpretation that these depths are dominated by the superparamagnetic particles. When superparamagnetic particles are predominant, they dominate the susceptibility and SPCDM signals, but the frequency effect is little because there are little variations of the grain size distribution of the sample. In terms of bioprecipitation, this may be reflecting that most of the Fe-bearing particles are being used by microorganisms.

Even though magnetic signatures are a result of the magnetic grain sizes, this investigation approach does not aim to estimate the magnetic grain sizes and rather seek for these grains fingerprints. Moreover, the complex history of the site reminds us to expect an assemblage of grain sizes. This aspect enhances the usefulness of our quantitative interpretation procedures, which isolates and quantifies the ultrafine content.

In general, the distribution of SP minerals correlates well with the detected methanogens, suggesting that the SP particles of magnetite at these depths are anaerobically produced by iron-reducing dissimilatory microorganisms such as, *Geobacter* and *Geothrix*. There may be further syntrophy with methanogens such as *Methanoseta* where Geobacter can further be involved in the DIET mechanism. Microbial analysis (Figure 1) supports the hypothesis of DIET as the methane producing mechanism at depths where superparamagnetic particles achieve highest concentrations. We propose a conceptual model of magnetic particles size range associated with the DIET hypothesis. Figure 7 illustrates the transformation of ferrihydrite into magnetite by iron reducing bacteria and the electron transfer to methanogens archaea. The DIET zone in this case is identified by a region of high SP content, surrounded by coarser particles within the SP-SSD threshold.

Other non-DIET reactions with Fe(III) reducing bacteria such as *Geothrix* with may also have a role in the production of magnetite (Klueglein et al., 2013) and there may be some syntrophy with *Methanosaeta* (Sutcliffe et al., 2018).

**CONCLUSION**

Magnetic properties measurements revealed the ultrafine magnetic particles occurrence in a brownfield site. The distribution of superparamagnetic concentration correlates well with the detected methanogens in gas pockets, suggesting that the microbial activity producing methane is producing these ultrafine particles, different from the magnetic particles produced at other depths. The results presented here support the use of environmental magnetism techniques to investigate biogeochemical processes of anaerobic microbial activity. Possibly, this kind of superparamagnetic fingerprint can be found in non-active methanogenic basins but recorded by magnetic mineralogy once preserved.

**DATA AVAILABILITY STATEMENT**

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.
AUTHOR CONTRIBUTIONS

AU conducted the magnetic susceptibility measurements (frequency and temperature dependence), and conducted the multi-frequency analysis. AU has been studying the site for many years and for this study she planned the magnetic investigation and interpreted the results with the co-authors. CA was the project’s PI and contributed discussing the results and writing/revising many parts of the manuscript. AL conducted the magnetization decay and FORCs and MR conducted the hysteresis measurements. FORC and hysteresis were also supervised and discussed with MM. GT, an undergraduate student, conducted the thermomagnetic measurements. RD participated in the research at the site collaborating with the microbiological analysis. The results were discussed with all co-authors, who also wrote/revised the manuscript.

ACKNOWLEDGMENTS

The authors thank FAPESP (grant # 2013/229912) and CNRS (project NanoEnvi-GET). We would like to acknowledge the laboratories where measurements were taken: USPMAG for thermomagnetic and time-dependent IRM, Institut National des Sciences Appliquées (INSA)—Toulouse for hysteresis, Institut de Physique du Globe de Paris for FORC and LabCore for frequency dependence susceptibility (Oceanography Institute, University of São Paulo).
