Abstract – We study linear response and nonequilibrium steady-state thermoelectric transport through a single-level quantum dot tunnel coupled to two reservoirs held at different temperatures as well as chemical potentials. A fermion occupying the dot interacts with those in the reservoirs by a short-ranged two-particle interaction. For parameters for which particles flow against a bias voltage from the hot to the cold reservoir this setup acts as an energy conversion device with which electrical energy is gained out of waste heat. We investigate how correlations affect its efficiency and output power. In linear response the changes in the thermoelectric properties can be traced back to the interaction-induced renormalization of the resonance line shape. In particular, small to intermediate repulsive interactions reduce the maximum efficiency. In nonequilibrium the situation is more complex and we identify a parameter regime in which, for a fixed lower bound of the output power, the efficiency increases.

Introduction. – Quantum dots (QDs) are considered as high-potential solid-state energy conversion devices to gain electrical energy out of waste heat [1]. In a minimal setup electrons from a hot right reservoir (at temperature $T_R$) are transported via a weakly coupled QD to a cold left one (at $T_L$) against a bias voltage $V = \mu_L - \mu_R \geq 0$. Here $\mu_\alpha$ denotes the chemical potential of reservoir $\alpha = L, R$ and we use units in which the elementary charge $e = 1$. Within linear response, that is for small temperature differences and small bias voltages, one aims at a high efficiency $\eta$ of energy conversion. It is defined as $\eta = P/|I_h|$, with the output power $P = V|I_c|$ and the charge/heat currents $I_{c/h}$ (see footnote 1). As a measure of $\eta$ in QD setups one often uses the so-called figure of merit $ZT$ [1]; the larger $ZT$, the closer $\eta$ comes to its upper bound, the Carnot efficiency $\eta_C$. We here neglect the contribution of the phonon thermal conductance to $ZT$ and focus on the electronic degrees of freedom. The figure of merit is inversely proportional to the Lorenz number. Under the assumption of scattering processes which on the scale $T_R \approx T_L \approx T$ only weakly depend on energy the Wiedemann-Franz law states that the latter is a material independent number. This limits the electronic $ZT$ in bulk materials which obey this law. In QDs due to the strong energy dependence of the transmission close to transport resonances [1–3] the Wiedemann-Franz law does not apply as long as the temperature is larger than the resonance width $\Gamma$. Therefore, in transport through dots with sharp resonances a large figure of merit and thus a high efficiency can be realized [1–4]. Equivalently, QDs can be used as efficient solid-state systems for cooling of nanoelectronic devices [5].

Due to the confinement of electrons in QDs to meso- or nanoscopic regions, the local Coulomb interaction becomes a relevant energy scale. This two-particle interaction strongly alters the line shape of resonances and thus the thermoelectric properties [3,4,6]. For example, the Kondo effect, resulting from correlated spin fluctuations, leads to a very sharp many-body resonance of width much smaller than the noninteracting $\Gamma$. This has crucial consequences for thermoelectric transport [7–14]. Even in the absence of the Kondo effect correlated charge fluctuations affect the line width as was worked out in detail for the interacting resonant level model (IRLM) [15–20]. For weak to intermediate local Coulomb repulsions the interaction renormalized width $\Gamma_{\text{ren}}$ is increased compared

We are only interested in the part of the parameter space in which our setup can be used to gain electrical energy. We thus define $\eta$ and $P$ such that both are positive under this condition (absolute values of the currents).
to the noninteracting one $\Gamma$, while for strong repulsive interactions as well as attractive ones $\Gamma_{\text{ren}} < \Gamma$. Effectively attractive interactions might be realized in molecular QDs with strong local electron-phonon coupling [10]. The consequences of the interaction renormalized resonance line shape for the thermoelectric transport properties were not discussed so far. We fill this gap and show that the parameter dependence of $\eta$ and $P$ can be understood in terms of the line width renormalization. We provide approximate analytical results for the efficiency and the output power which for small two-particle interactions agree very well with numerical data. For weak repulsive interactions the maximum efficiency decreases, it increases for attractive ones. Depending on the temperature regime considered the two-particle interaction can lead to an increase or to a decrease of the power at maximum efficiency.

In linear response the output power is of order $\Delta T^2$, with $\Delta T = T_L - T_R < 0$, and thus small (see below). Depending on the precise technological conditions under which the QD “heat engine” is supposed to perform (fixed or tunable $\Delta T$, limited or unlimited supply of heat, scalability in parallel or series, etc.) it might be meaningful to maximize $P$ instead of $\eta$ by varying the model parameters and the voltage at fixed temperatures, with $[\Delta T]$ not necessarily being small. Within the framework of nonequilibrium thermodynamics studying the efficiency at maximum power of general heat engines is an active field of current research [21–27]. In this context the non-interacting resonant level model in the limit of vanishing field of current research [21–27]. In this context the non-interacting resonant level model in the limit of vanishing level-reservoir coupling was studied as a toy model [28]. Even questions such as “what is the optimal efficiency reachable for the power being larger than a given lower bound” might be of interest. Computing the efficiency at maximum power and answering questions of the above type requires access to the full nonequilibrium (in $V$ and $\Delta T$) steady-state properties [29]. For microscopic models of QDs with local two-particle correlations achieving this presents a formidable challenge; for a recent review, see, e.g., ref. [30]. In particular, this holds if nonperturbative effects in both the level-reservoir coupling as well as the two-particle interaction become crucial as it is the case in the IRLM [15–20].

Only recently a very flexible nonperturbative tool was developed which allows to treat the full-fledged nonequilibrium steady state of the IRLM [19,31,32] at weak interactions. It is based on Keldysh Green functions [33] and the functional renormalization group approach to quantum many-body physics [34]. Here we apply this method to study the efficiency and power output of the IRLM “heat engine” beyond linear response. Broadly speaking the effect of the interaction on the efficiency (at maximum power) is similar to the one found in linear response. By closer inspection we identify a situation in which a weak repulsive interaction can lead to an increase of the efficiency by a few percent at fairly large power output.

**Quantum dot model.** – Our model Hamiltonian sketched in fig. 1 consists of three parts $H = H_T + H_D + H_c$.

![Fig. 1: (Color online) Sketch of the investigated model.](image)

The two spinless reservoirs are given by

$$H_T = \sum_{k,\alpha} \epsilon_k c_{k,\alpha}^\dagger c_{k,\alpha},$$

with fermionic ladder operators $c_{k,\alpha}^{(1)}$, where $k$ denotes a set of quantum numbers characterizing the reservoir states. To disentangle effects of the reservoir band structure encoded in the dispersion $\epsilon_k$ and the correlations on the thermoelectric properties we assume structureless reservoirs with an energy independent density of states $\rho$ between $-D$ and $D$ and the bandwidth $2D$ being much larger than any other energy scale. The reservoirs are in grand canonical equilibrium with $T_o = 1/\beta_o$ and chemical potentials centered around zero: $\mu_L = -\mu_R = V/2$ (with $h = k_B = e = 1$). The dot part of $H$ is given by $H_D = \epsilon_n$, with the dot occupation number operator $n = d^\dagger d$. The energy $\epsilon$ of the level is assumed to be tunable; in experiments this is achieved by applying a voltage to a properly fabricated gate. Finally, the coupling reads

$$H_c = t \sum_{k,\alpha} \left( \epsilon_k^c c_{k,\alpha}^\dagger d + \text{H.c.} \right) + u \left( n - \frac{1}{2} \right) \sum_{k,\alpha} \epsilon_{k,\alpha}^c c_{k,\alpha}^\dagger c_{k,\alpha}^\dagger;$$

where $\ldots \ldots$ denotes normal ordering. This and the shift of the dot occupancy by $-1/2$ ensures that $\epsilon = 0$ corresponds to half dot filling. For simplicity we assume the tunnel couplings to the left and right reservoir $t$ to be equal; similarly for the two-particle interactions $u$ to the left and right. We note that within our approach to the many-body problem these restrictions can easily be relaxed. We use the dimensionless interaction $U = \mu u$.

**Thermoelectric transport at $U = 0$.** – For $U = 0$, transport through the dot is characterized by a Breit-Wigner transmission resonance,

$$\tau(\omega) = \frac{\Gamma^2}{(\omega - \epsilon)^2 + \Gamma^2},$$

with $\Gamma = |U|/\epsilon$. For $\epsilon = 0$ it is Lorentzian. At $\epsilon > 0$ the transmission becomes cutoffed on the high-energy side of the resonance.
of width $\Gamma = 2\pi \rho t^{2}$. The steady-state charge current $I_{c}$ (leaving the left reservoir) and heat current $I_{h}$ (entering the right reservoir) can be computed using the Landauer-Büttiker formalism,

$$I_{c} = \frac{1}{2\pi} \int d\omega \tau(\omega) [f_{L}(\omega) - f_{R}(\omega)],$$  
$$I_{h} = \frac{1}{2\pi} \int d\omega (\omega - \mu_{L}) \tau(\omega) [f_{L}(\omega) - f_{R}(\omega)],$$

with the Fermi functions $f_{\alpha}(\omega) = [e^{(\omega - \mu_{\alpha})/T} + 1]^{-1}$. We express the energy integral in $I_{c}$ in terms of the digamma function $\Psi(0, z)$ as

$$I_{c}(\epsilon) = \frac{1}{2\pi} \text{Im} \left[ \Psi \left( \frac{1}{2}, \frac{i}{2\pi T} \right) \right] - \pi T \sum_{m} \frac{1}{2} \int d\epsilon' \frac{I_{c}(\epsilon')}{\epsilon - \epsilon'},$$

and the heat current as a sum of the charge current and the Hilbert transformation of the latter

$$I_{h}(\epsilon) = (\epsilon - \mu_{R})I_{c}(\epsilon) - \frac{1}{\pi} \int d\epsilon' \frac{I_{c}(\epsilon')}{\epsilon - \epsilon'}.$$  

(7)

In eqs. (6) and (7) $\Gamma$ can be scaled out (taken as the unit of energy) and $\eta$ as well as $P$ can be investigated as functions of the model parameter $\epsilon/\Gamma$, the external bias voltage $V/\Gamma$, and $T_{L/R}/\Gamma$. In analogy to studies on periodic heat engines in thermodynamics we assume that $T_{L/R}$ are fixed by the environment. With $|\Delta T|/\Gamma$ not necessarily being small we cannot resile to the linear regime. Figure 2 shows $P = V|I_{c}|$ in the $(\epsilon, V)$-plane for $T_{L}/\Gamma = 1$ and $T_{R}/\Gamma = 20$. It has a unique maximum.

To set the stage for more general considerations we first consider the limit $\Gamma \to 0$ [28]. The second term in eq. (7) is of higher order in $\Gamma$ as compared to the first one and can be neglected. As a consequence charge and heat flow are “perfectly coupled” (proportional to each other); for $\Gamma \to 0$ the energy of every particle coming from the dot level becomes sharp and is fixed at $\epsilon$ [28]. For applications it is meaningful to maximize the output power—the maximum is denoted by $P_{m}$ in the following—and study the efficiency at maximum power $\eta_{mp}$ as a function of $T_{L/R}$. The optimization is performed with respect to the level energy $\epsilon$ and the externally applied voltage $V$ both being parameters which in experiments on QDs can routinely be varied with high precision. As shown analytically in ref. [28] for $\Gamma \to 0$, $\eta_{mp}$ and $P_{m}$ are functions of $T_{L}/T_{R}$ only and can thus be written as functions of the Carnot efficiency $\eta_{C} = 1 - T_{L}/T_{R} = |\Delta T|/T_{R}$.

We now return to $\Gamma > 0$ and numerically maximize the output power with respect to $\epsilon$ and $V$ using eqs. (6) and (7). Both, $\eta_{mp}$ and $P_{m}$ are no longer functions of $\eta_{C}$ only. This becomes apparent from fig. 3 which shows $\eta_{mp}$ and $P_{m}$ as functions of $T_{L}/T_{R}$ and $\eta_{C}$. Only in the limit of large $T_{L}/T_{R}$, that is small $\Gamma$, the dependence on $T_{L}/T_{R}$ drops out. For small $T_{L}/T_{R}$ rather large $\eta_{C} = |\Delta T|/T_{R}$ (close to 1) are required to obtain a sizable efficiency at maximum power.

Expanding eqs. (6) and (7) to lowest order in $\Delta T/T$ and $V/T$ we obtain linear response results [4]. The currents follow from the Onsager matrix containing the conductances:

$$
\begin{pmatrix}
I_{c} \\
I_{h}
\end{pmatrix}
=

\begin{pmatrix}
G_{c} & G_{c}^{\Delta T} \\
G_{h}^{\Gamma} & G_{h}
\end{pmatrix}
\begin{pmatrix}
V \\
\Delta T
\end{pmatrix},
$$

(8)

The Onsager (time-reversal) symmetry gives $G_{h}^{\Gamma} = TG_{c}^{\Delta T}$, with $T = T_{L} + T_{R}$, and the independent matrix elements can be written as [4]

$$
G_{c} = \frac{\Gamma}{8\pi^{2}T} \left[ \Psi \left( 1, \frac{\pi + w}{2\pi} \right) + \text{c.c.} \right],
$$

(9)

$$
G_{c}^{\Delta T} = -\frac{i\Gamma}{8\pi^{2}T} \left[ w \Psi \left( 1, \frac{\pi + w}{2\pi} \right) - \text{c.c.} \right],
$$

(10)

$$
G_{h} = \frac{\Gamma}{2\pi} \left[ \frac{\Gamma}{T} - \frac{1}{4\pi} \left[ w_{2} \Psi \left( 1, \frac{\pi + w}{2\pi} \right) + \text{c.c.} \right] \right],
$$

(11)

with the trigamma function $\Psi(1, z)$ and $w = (\Gamma + i\epsilon)/T$. In linear response one aims at a large $\eta$. Independently of the model considered one first maximizes $\eta = V|I_{c}|/|I_{h}|$ with respect to $V$ [22,25] using eq. (8) leading to

$$
\eta_{0} = \sqrt{\frac{ZT + 1}{ZT + \frac{1}{T}}} - 1, \quad ZT = \frac{(G_{c}^{\Delta T})^{2}T}{G_{c}G_{h} - (G_{c}^{\Delta T})^{2}T},
$$

(12)
The maximum is reached for a voltage of order $\Delta T$ and the linear response regime is not equal. Equation (12) constitutes the relation between the efficiency and the figure of merit $ZT$ announced in the introduction: the latter being expressible in terms of the conductances. We can now be more precise: $ZT$ is a measure for the linear response efficiency maximized with respect to $V$. For $ZT \to \infty$, $\eta_0$ approaches the linear response Carnot efficiency $|\Delta T|/T$ which constitutes an upper bound for all thermodynamic efficiencies. The power corresponding to $\eta_0$ is given by

$$P_0 = \frac{TG_h}{\sqrt{ZT + 1} + 1} \left( \frac{\Delta T}{T} \right)^2$$

and thus of order $(\Delta T)^2$; one factor $\Delta T$ comes from the voltage at which the maximum efficiency is reached and the other from the charge current. In the limit $ZT \to \infty$, with $\eta_0 \to \eta_C$, the prefactor of $P_0$ vanishes.

We now return to our specific model and similarly to the nonequilibrium case above we first consider the limit $\Gamma \to 0$. Independently of $\epsilon \neq 0$, one finds $ZT \sim 1/\Gamma$ [4] and thus $\eta_0 \to \eta_C$ [28]. Furthermore, $G_h \sim \Gamma$ and $P_0 \to 0$.

For $\Gamma > 0$ we numerically maximize $\eta_0$ (in addition) with respect to $\epsilon$ using eqs. (8)–(11) [4]. The resulting efficiency $\eta_m$ and power at maximum efficiency $P_{\text{me}}$ as functions of $T/\Gamma$ are shown in fig. 4. As discussed above for $\Gamma \to 0$, that is for large $T/\Gamma$, $\eta_m$ approaches Carnot efficiency and $P_{\text{me}}/\Delta T^2$ vanishes. The latter also vanishes for $T/\Gamma \to 0$ and is thus a nonmonotonic function with a maximum at $T \approx \Gamma$. Our calculations show that for small $T$ the level energy at which optimal efficiency is reached approaches a constant. Using this and the expansions of eqs. (9)–(11) we obtain $T G_h \sim T^2$ and $ZT \sim T^2$. Thus, $P_{\text{me}}/\Delta T^2 \sim T^2$ (see the inset of fig. 4).

**Thermoelectric transport at $U \neq 0$.** To investigate the linear response and nonequilibrium steady-state transport properties in the presence of two-particle correlations we use a technique which is based on nonequilibrium Keldysh Green functions [33] and the functional renormalization group approach to quantum many-body physics [34]. In this one derives an exact infinite hierarchy of coupled differential equations for the many-body self-energy and the effective $n$-particle interactions (one-particle irreducible vertex functions). The derivative is taken with respect to a low-energy cutoff and the set of equations has to be integrated from infinity to zero. Concrete calculations require truncations. We apply the lowest-order approximation in which only the self-energy flow is kept. It was earlier used to study the IRLM for $|U| < 1$ in equilibrium as well as the charge current in steady-state nonequilibrium [19,31,32]. We refrain from giving any technical details and instead refer the interested reader to refs. [19] and [32].

As its main effect the two-particle interaction generates a renormalization group flow of the hybridization $\Gamma/2$ to the individual reservoirs. For the left one it is cut off by the largest of the energy scales $|\epsilon - \mu_L|$, $T_L$, and the total hybridization; for the right one, one has to replace the index $L$ by $R$ [19,31,32]. This leads to a power-law scaling $\Gamma_{\text{ren}}/\Gamma \sim (s/D)^{-\nu(U)}$, with the corresponding largest scale $s$ (still much smaller than $D$) and the $U$-dependent exponent $\nu$. To leading order one finds $\nu(U) = 2U$ [15,18–20,31,32,38]. This correlation effect cannot be captured by perturbative (in either $U$ or $\Gamma$) approaches. In a general nonequilibrium setup $\Gamma_{\text{ren}}^{\text{L}} \neq \Gamma_{\text{ren}}^{\text{R}}$, even in the case of equal bare hybridizations. To exemplify how the renormalization manifests in physical observables we consider the linear response $(V, \Delta T \to 0)$ charge conductance $G_c$ as a function of $\epsilon$ close to the resonance (at $\epsilon = 0$) and $T = 0$ [17,19,20]. The largest scale cutting off the renormalization group flow of the hybridizations is given by $\Gamma$. Using the above scaling law one concludes that the resonance in $G_c$ has the width

$$\Gamma_{\text{ren}} = W = \Gamma \left( \frac{2\Gamma}{D} \right)^{-2U}$$

which defines the emergent energy scale $W$. The resonance becomes wider for weak (to intermediate [17]) repulsive interactions but more narrow for attractive ones. To illustrate how $\Gamma_{\text{ren}}$ changes when two or more of the energy scales are of the same order [19,31,32] we consider $T \geq W$.

In this case $\Gamma_{\text{ren}} \approx W(T/W)^{-2U}$; see fig. 1 of ref. [32]. Since $|U| \ll 1$ the correction to $W$ is of order one as long as $T$ does not exceed $W$ by several orders of magnitude. Further down this will become crucial.

We start the discussion of our results of correlation effects on the efficiency and power considering linear response. The symbols in fig. 4 show the maximum efficiency $\eta_m$ (maximized with respect to $V$ and $\epsilon$) and the power at maximum efficiency $P_{\text{me}}$ for $U = \pm 0.1/\pi$. [57003-p4]
obtained by numerically integrating the renormalization group equations and computing the charge and thermal currents. For weak repulsive interactions \( \eta_\text{me} \) is reduced compared to the noninteracting result, while it is increased for weak attractive ones. Depending on the temperature regime considered, the interaction enhances or reduces \( P_\text{me} \). These results can be understood analytically by employing the above discussed energy scale dependence renormalization of the resonance width. For \( U = 0 \) the level energy \( \epsilon \) at which the maximum efficiency is reached is of the order of a few \( T \) at large \( T \) [4] while it saturates at a constant of order \( \Gamma \) for small \( T \). This also holds for small \( |U| \). Thus, eq. (14) gives a very good estimate of the renormalized hybridization for all temperatures shown in fig. 4. This motivates us to replace \( \Gamma \) in the noninteracting expressions eqs. (8)–(11) for the charge and heat currents by \( W \), eq. (14). The corresponding results for \( \eta_\text{me} \) and \( P_\text{me} \) are shown as dashed lines in fig. 4. As expected they show excellent agreement with the numerical data. The deviations at \( T/\Gamma \gtrsim 1 \) are consistent with the finite-\( T \) correction to \( W \) discussed above. As our approximate approach is restricted to \( |U| \ll 1 \) we cannot access the regime of large interactions. It is known that \( \Gamma^\text{ren} \) is a nonmonotonic function of \( U > 0 \) and for large repulsive interactions one finds \( \Gamma^\text{ren} < \Gamma \) [17,18]. This follows from a second-order term \( \sim -U^2 \) which dominates for \( U > 1 \) and changes the sign of the exponent \( \nu \) [18]. Based on our above results it is thus reasonable to assume that for large repulsive interactions \( \eta \) will be larger than in the noninteracting case. It would be

---

\[ \text{Fig. 5: (Color online) Efficiency at maximum power (upper panel) and the maximum power (lower panel) for different sets of } T_{L/R} \text{ as functions of } U. \text{ The lines are guide to the eyes. The data are scaled by the given factors.} \]

---

\[ \text{Fig. 6: (Color online) Interaction } U \text{-dependence of the largest efficiency obtainable with } P \geq P_b \text{ for } T_L/\Gamma = 1 \text{ and } T_R/\Gamma = 20 \text{ (for details see the text). The line is an Akima spline interpolating between the computed data points (crosses: } T_{aux} = \infty; \text{ circles: } T_{aux} = 0). \text{ The efficiency can be raised by a few percent by turning on a small repulsive interaction.} \]

very interesting to explicitly verify this using a method complementary to ours. We next leave the linear response regime. Figure 5 shows the \( U \)-dependence of the maximum power \( P_m \) and the efficiency at maximum power \( \eta_{\text{mp}} \) for different sets of \( T_{L/R} \) obtained numerically using our nonequilibrium many-body method. In analogy to the maximum efficiency in linear response, \( \eta_{\text{mp}} \) is a decreasing function of \( U \). A similar analogy to the linear response results for \( P_{\text{me}} \) (see fig. 4) holds for the maximum power \( P_m \). It is a decreasing function of \( U \) for temperatures \( T_{L/R} \) smaller than \( \Gamma \) and an increasing one for \( T_{L/R}/\Gamma \gg 1 \). For intermediate temperatures we find nonmonotonic behavior. We have also studied the \( U \)-dependences of the maximum (with respect to \( V \) and \( \epsilon \)) efficiency and the corresponding output power beyond the linear response regime. They are qualitatively similar to the results for \( \eta_{\text{mp}} \) and \( P_m \) shown in fig. 5. We finally show that under special conditions the decrease of the efficiency for repulsive interactions can be overcome. To find those we exploit that for appropriate temperatures \( T_{L/R} \) the maximum power increases with \( U \); this already sets the first requirement, namely on \( T_{L/R} \). We next assume that our “heat engine” has to produce at least a certain minimum output power which is a sensible constraint if we are interested in charging a battery. For fixed \( T_{L/R} \) we proceed as follows: as our lower bound of the power \( P_b \) we for simplicity take the maximum power at \( U = 0 \). Varying \( \epsilon \) and \( V \) we then search for the largest efficiency \( \eta_{>} \) at fixed \( U > 0 \) with \( P \geq P_b \). As this is a numerically demanding procedure — remind that for every parameter set the currents \( I_{L/R} \) have to be computed numerically solving coupled differential flow equations—we restrict ourselves to one of the temperature sets of fig. 5, namely \( T_L/\Gamma = 1 \) and \( T_R/\Gamma = 20 \). The \( U \)-dependence of \( \eta_{>} \) is shown in fig. 6. Under the above conditions the efficiency increases with increasing interaction even at small \( U \). At larger \( U \) the generic decrease of the efficiency with increasing \( U \) takes over.

---

\[ \text{57003-p5} \]
leading to a maximum at $U \approx 0.005$. It is known [19,31] that using our approximate renormalization-group–based many-body method one achieves quantitative agreement with numerically exact results [17] for charge transport of the IRLM up to significantly larger $U$. To demonstrate the robustness of the subtle efficiency gain which, in addition, involves heat transport, we considered two different cutoff procedures: the reservoir cutoff with temperature $T_{\text{aux}} = \infty$ in the auxiliary leads [32], used also for the other results presented here, as well as with $T_{\text{aux}} = 0$ [19]. We find excellent agreement. We expect that the precise value of the few percent optimal efficiency gain and its position are weakly affected by higher-order terms not captured by us.

Summary. – We have discussed the charge and heat transport properties of an elementary single-level quantum dot “heat engine” which can be used to convert waste heat into electrical energy. We have studied the linear response and nonequilibrium steady-state thermoelectric properties in the absence of local Coulomb correlations. The efficiency and output power of this device was investigated in all details. We next included the local two-particle interaction which in meso- or nanoscopic devices is an important energy scale. Using a flexible approximate many-body method which can be applied in linear response as well as the in the nonequilibrium steady state we were able to present a comprehensive picture of the correlation effects on the efficiency and output power.
