EFFECTS OF MULTISENSORY STIMULATION WITH VIRTUAL REALITY THERAPY ON PSYCHOLOGICAL PARAMETERS IN PATIENTS WITH STROKE

Lavinia Raluca Butuc, Liviu Lazar

University of Oradea, Faculty of Medicine and Pharmacy

ABSTRACT

This article presents a systematic analysis with the intention of showcasing the effects of the multi-sensory stimulation therapy with virtual reality on psychological parameters in patients with stroke. The main objective of this study was to determine the effectiveness of this multisensory therapy on the patient's psyche, especially the impact on cognitive function, as well as the impact on daily activities and the assessment of possible negative influences.

Keywords: multi-sensory stimulation therapy with virtual reality, medical recovery, software, plegia, virtual games, virtual environments

INTRODUCTION

In the last decade, the number of patients who have suffered strokes or traumatic injuries has increased considerably. A series of studies have shown that medical recovery based on repetitive movements, focused mainly on carrying out different tasks is effective in the improvement of movement abilities (1). Stroke is often accompanied by anxiety and depression in patients. Frequently, patients diagnosed with stroke tend to conceal subtle thoughts and feelings, often hiding them from their doctors, for fear of being subjected to common depression-related prejudices (2). Multisensory stimulation with virtual reality therapy is defined as a virtual, immersive and three-dimensional environment which occurs in real time and stimulates even patients with physical and cognitive disability into active participation (3).

MATERIAL AND METHOD

To determine the degree of anxiety and depression present following stroke we applied the following assessment scales: Geriatric Depression Scale (GDS), Hamilton Anxiety Rating Scale (HAM-A) and Beck Anxiety Inventory (BAI). The questionnaires focused on the evolution of depression and anxiety, physical activity and psychological support. We conducted a prospective randomized study involving two homogeneous lots of patients with stroke, namely: a study group consisting of 30 patients who underwent physiokinetic therapy and multisensory stimulation therapy with virtual reality, and the control group in which there were 36 of patients under physiokinetic therapy but without multisensory stimulation therapy with virtual reality (Figure 1 and Table 1).

| Gender | Study group | Control group |
|--------|-------------|---------------|
| No.    | %           | No.           | %            |
| Female | 11          | 36.67         | 12           | 33.33 |
| Male   | 19          | 63.33         | 24           | 66.67 |
| Total  | 30          | 100.00        | 36           | 100.0 |

Men prevailed in both groups, the male / female ratio being 1.7: 1 in the study group, respectively 2:
1 in the control group. There are no significant differences between the two groups in terms of sex distribution ($p = 0.7784$) (Table 1).

In the study groups the majority of patients were over 50 years old (73.33% and 80.56% respectively), without significant differences between the two groups ($p = 0.126$) (Figure 2).

**TABLE 2. The distribution by age**

| Age      | Study group | Control group |
|----------|-------------|---------------|
| £ 40 years | 3 (10.00%)  | 1 (2.78%)     |
| 41-50 years | 5 (16.67%)  | 6 (16.67%)    |
| 51-60 years | 10 (33.33%) | 11 (30.56%)   |
| > 60 years  | 12 (40.00%) | 18 (50.00%)   |

**TABLE 3. The distribution by type of stroke**

| Type of stroke | Study group | Control group |
|---------------|-------------|---------------|
| Hemorrhagic   | 13 (43.33%) | 16 (44.44%)   |
| Ischemic      | 17 (56.67%) | 20 (55.56%)   |

Figure 3 and Table 3 show that over 55% of the patients in both groups suffered from stroke ischemic (56.67% and 55.56% respectively) ($p = 0.9285$).

The inclusion criteria were as follows: patients with ischemic and hemorrhagic stroke aged between 24 and 75 years; the time span of the vascular event being: I: between 3 and 6 months; II: between 6 months – 1 year and III: over one year.
year; patients with stroke that is confirmed by clinical examinations and paraclinical investigations and patients who have expressed a desire to be treated with multisensory stimulation therapy with virtual reality and gait testing and the exclusion criteria were: patients less than 24 years old and older than 75 years; patients with visual and hearing impairments who could not interact with multisensory virtual reality therapy and gait testing; patients with mental illness.

All patients were informed about the study and gave their consent by signing the informed consent form.

The study was conducted in the Bâile Felix Medical Recovery Hospital from November 2016 to August 2017. Patients were assessed when they were included in the study and after 6 months.

RESULTS AND DISCUSSION

The results regarding the patients’ perception of depression are shown in Table 4 and Figure 4, as follows:

As can be seen initially, the degree of geriatric depression has had normal outcomes for 30.00% of the patients in the study group, respectively 27.78% in the control group (p = 0.8440) and severe depression for 10.00% and 13.89% of the patients, respectively (p = 0.6323). After 6 months the degree of geriatric depression has had a normal result at 70.00% of the patients in the study group, respectively 47.22% in the control group (p = 0.0643) and severe depression at 6.67% in the study group, respectively 11.11% of the patients in the control group (p = 0.5353).

The mean GDS score in the Study group decreased within 6 months from 12.83 to 8.90 (p = 0.0037) and in the Control group from 13.39 to 12.03 (p = 0.1525). Thus the treatment effect on geriatric depression was 3 times higher in the Study group than in the Control group (ES = 0.78, ES = 0.26).

Although the presence of depression may go unnoticed, this is the most common psychiatric disorder present in elderly patients, thus being one of the main grounds in medical examination (Blazer, 2003) (4).
Perception of anxiety

Evolution of the values obtained by measuring the anxiety level for the two groups is presented in Table 5 and Figure 5 below:

**TABLE 5. Evolution of anxiety - Hamilton scale**

|                      | Study group | Control group |
|----------------------|-------------|---------------|
|                      | Baseline    | At 6 months   | Baseline    | At 6 months   |
| No                   | %           | No            | %           | No            | %           |
| Low anxiety          | 10          | 33.33         | 18          | 60.00         | 11          | 30.56       | 13          | 36.11       |
| Moderate anxiety     | 14          | 46.67         | 9           | 30.00         | 17          | 47.22       | 17          | 47.22       |
| Anxiety with worrying potential | 6          | 20.00         | 3           | 10.00         | 8           | 22.22       | 6           | 16.67       |
| Average±SD           | 23.27±8.50  | 19.20±7.73    | 23.97±7.55  | 21.92±8.53    |
| ES                   | 0.48        | 0.27          |

We can notice that the severity of anxiety assessed using the Hamilton scale is mild, being initially present in 33.33% of the patients from the study group and 36.11% of the patients in the control group (p=0.8128). We found out that 16.67% of the patients in the study group had severe anxiety, compared to 11.11% of the patients in the control group (p = 0.5154). Regarding anxiety evaluated at 6 months follow-up, it was observed that 40.00% of the patients in the study group suffered from mild anxiety, the results being similar for the control group, respectively 41.67% (p=0.8915). After the same period of time, 13.33% of the patients from the study group, respectively 11.11% of the patients from the control group were rated as suf-
In the Study group, the Hamilton score decreased in 6 months from 19.73 to 18.10 (p = 0.0526) and in the Control group from 19.69 to 19.00 (p = 0.3833). The effect of treatment on anxiety was 2.3 times higher in the Study group versus the Control group (i.e. ES = 0.46, ES = 0.20, respectively).

Table 6 and Chart 6 below show the results calculated for Beck Anxiety Scale (BAI) scores.

**TABLE 6. Evolution of anxiety – Beck anxiety inventory**

|                          | Study group | Control group |
|--------------------------|-------------|---------------|
|                          | Baseline    | At 6 months   | Baseline    | At 6 months   |
|                          | No.         | %             | No.         | %             |
| Mild anxiety             | 10          | 33.33         | 12          | 40.00         |
|                          |             |               | 13          | 36.11         |
|                          |             |               | 15          | 41.67         |
| Moderate anxiety         | 15          | 50.00         | 14          | 46.67         |
|                          |             |               | 19          | 52.78         |
|                          |             |               | 17          | 47.22         |
| Severe anxiety           | 5           | 16.67         | 4           | 13.33         |
|                          |             |               | 4           | 11.11         |
|                          |             |               | 4           | 11.11         |
| Average±SD               | 19.73±3.53  | 18.10±2.81    | 19.69±3.43  | 19.00±3.24    |
| ES                       | 0.46        | 0.20          |

Initially, as assessed according to the Beck Anxiety Inventory scale, anxiety was rated as low in 33.33% of the patients in the study group and 30.56% of the patients in the control group (p=0.8113) and as worrying potential in 20.00% of the patients in the study group and 22.22% of patients in the control group (p=0.8274). After 6 months the anxiety was low at 60.00% of patients in the Study group and 36.11% of patients included in the Control group, respectively (p = 0.0547), while the anxiety with worrying potential was present in 10.00% of the patients in the Study group and 16.67% of patients included in the Control group (p = 0.4353), respectively.

In the Study group, mean Beck anxiety inventory scores decreased in 6 months from 23.27 to 19.20 (p = 0.0572) and in the Control group from 23.97 to 21.92 (p = 0.2840) and the effect of treatment on anxiety was 1.8 times higher in the Study group than in the Control group (ES = 0.48, ES = 0.27).

The cause of depression is considered to be a biochemical imbalance in the brain. Studies on identical twins indicate that genetic factors contribute 30-42% to variations in the symptoms of anxiety and depression. In other words, under stressful conditions, vulnerable patients will become anxious and depressed just as other patients are prone to diabetes or high blood pressure. However, there are also cases where biochemical changes in the brain arise without a specific cause. According to the World Health Organization, since 2001 it has been estimated that one in four people is prone to develop neurological or mental health problems throughout their lives. Moreover, about 350 million people worldwide suffer from depression and this is also the main mental health problem encountered in adolescents and young people, according to the same World Health Organization (5).

A series of permanent disorders associated with coordination and movement, attention and especially memory can cause stroke and can also generate depression symptoms, all of which have repercussions on patient recovery.
It is estimated that 30-40% of stroke survivors develop a certain level of functional dependence, which then requires assistance in performing basic Activities of Daily Living: (ADLs) (6).

In the first place in the prevalence of mental illness, anxiety disorder are 17% and the risk of being present at any time of life increases to 25%, most frequently in women than in men in a ratio of 2:1 (Kessler) (7). The causes of anxiety disorders are not fully known, but environmental, biological and psychosocial factors are involved. However, in the emergence of these disorders there is a certain genetic predisposition. On the other hand, comorbidity with other psychiatric disorders such as the presence of mood disorders is very common (8).

Computer programs have been proven to be an instrument with many advantages, including a great potential in aiding cognitive recovery (Lynch, 2002, Bracy, 1983) (9).

On the other hand, it was observed that as the patients surveyed in the Study group adapted to the new therapy by multisensory stimulation with virtual reality, the evolution of the treatment had favourable results, the anxiety being diminished significantly even after the 6 months which was confirmed not only by the statistical data but also by the discussions with the patients and after an assessment of their general health condition in comparison with the patients included in the Control group whose symptoms of anxiety and depression stagnated.

The need for medical recovery addresses is essential due to lesions and surgery and seeks to improve communication, muscle strength, coordination and mobility and these recovery treatments can lead to a substantial improvement in the patient’s ability to carry out their activities of daily and improve the quality of life (10).

Patients have feelings and moments when they feel positive emotions, for example: joy, compassion and love and this happens surprisingly even when stress is intense and things go wrong. However, many of these positive moments help patients to reduce the harmful effects that can occur especially when the body is stressed for a longer timeframe (11). Medical recovery has been characterized as a suitable tool for recovering cognitive functions of patients due to the fact that it allows for the setting of a contained and comprehensive environment. Moreover, the presence of a virtual environment can allow systematic evaluation of patients because all tasks in the virtual environment are performed and are related to activities of daily living (12).

CONCLUSIONS

The results have demonstrated that the use of multi-sensory stimulation therapy with virtual reality in a virtual environment can contribute to the medical recovery of patients with stroke.

The therapy used has promoted positive effects in the recovery of the following functions: anxiety disorder, fear, insomnia, behaviour, cognitive symptoms including memory and concentration, sensory somatic symptoms, depression, gastrointestinal, cardiovascular, genitourinary and vegetative symptoms, and muscle tension. The positive effects in the functional questionnaires used in the study have led to major improvements in the activities of daily living of patients.

Early observation and evaluation of depressive symptoms following a stroke are essential as they diminish the negative consequences on the recovery of patients with stroke.

The role of multi-sensory stimulation therapy with virtual reality in recovering patients included in the Study group had a motivational effect, being interesting and interactive through the games it put forward.

Our study demonstrates that medical recovery through multi-sensory stimulation with virtual reality is an effective, cheap and convenient therapy for hemiparesis patients similar to the results published by other authors (13).
