Abstract

Quantitative predictions from synthetic radiation diagnostics require consideration of all accelerated particles. For particle-in-cell (PIC) codes, this not only means including all macro particles but also taking into account the discrete electron distribution associated with them. This paper presents a general form factor formalism that allows quantifying the radiation from this discrete electron distribution. It enables computing the coherent and incoherent radiation self-consistently. Furthermore, a memory-efficient implementation is discussed that allows PIC simulations with billions of macro particles. The impact on the radiation spectra is demonstrated on a large scale LWFA simulation.

Keywords: particle-in-cell simulations, laser plasma acceleration, far field radiation, plasma physics, radiation diagnostics

1. Particle-in-cell codes as synthetic diagnostic for laser plasma accelerators

Laser plasma-based accelerators like laser wakefield accelerators (LWFA) offer various advantages over conventional accelerators such as their compact size due to their orders of magnitude larger acceleration gradient [1] resulting in GeV energy gains on centimeter scales [2–4], while allowing for compact electron bunch size [5] and low beam emittance [6]. Since these laser plasma accelerators operate in a highly nonlinear regime, particle-in-cell (PIC) codes are essential for understanding the plasma dynamics in these experiments [7, 8]. Making quantitative predictions on the measurable outcome of these experiments is done by so-called synthetic diagnostics. An essential form of these synthetic diagnostics are predictions on the radiation emissions [9–25]. However, most of these simulations lack quantitative predictions due to the small number of sample particles used (see [21] for details), but also due to an inconsistent treatment of the discrete nature of the electrons represented by macro particles in PIC codes. This renders quantitative comparisons to experiments impossible.

2. Spectrally resolved far field radiation using Liénard Wiechert potentials

The spectrally resolved far-field radiation emitted by a single electron can be computed by using Liénard-Wiechert potentials [26]. Based on the electrons position $\vec{r}$, velocity $\vec{\beta}$ and acceleration $\dot{\vec{\beta}}$ over time, the energy emitted per unit frequency $\omega$ and unit solid angle $\Omega$ in direction of the unit vector $\vec{n}$ computes as:

$$\frac{d^2 I}{d\Omega d\omega}(\omega, \vec{n}) = \frac{q^2}{16\pi^3\epsilon_0 c} \left| \int_{-\infty}^{+\infty} \vec{A} \cdot \chi \, d\tau \right|^2$$

(1)

with $\vec{A} = \frac{\hbar}{(1-\vec{n} \cdot \vec{\beta})\vec{\beta}}(\vec{\beta} - \vec{\beta}_0)$ and $\chi = e^{i(\omega t - \vec{n} \cdot \vec{r}(t)/c)}$ being the radiation amplitude and complex phase while $\epsilon_0$, $q$, and $c$ are the vacuum permittivity, the electron charge and mass.

For multiple electrons, the phase-relation between the various electrons needs to be taken into account by summation of the radiation amplitudes before taking the absolute square in Eq. 1:

$$\frac{d^2 I}{d\Omega d\omega}(\omega, \vec{n}) = \frac{1}{16\pi^3\epsilon_0 c} \left| \sum_{k=1}^{N} q_k \int_{-\infty}^{+\infty} \vec{A}_k \cdot \chi_k \, d\tau \right|^2$$

(2)
3. Applying form-factors to macro particles

3.1. Macro particle shapes in particle-in-cell codes

Particle-in-cell codes discretize the particle distribution function of the Vlasov equation using a finite number of sample particles [27, 28]. Due to the approximately hundred billion electrons that need to be considered in a common LWFA simulation, the number of simulated particles is reduced by combining electrons into so-called macro particles, that represent an ensemble of electrons. These macro particles have a spatial charge distribution, but only a singular momentum to avoid a spatial separation of the charge distribution over time. The common current deposition algorithms used in PIC codes treat the macro particles as a continuous time. The common current deposition algorithms used in PIC codes treat the macro particles as a continuous charge distribution [29, 30]. Using smoother and thus spatially more extended charge distributions for these macro particles yields less numeric noise in the electromagnetic fields. A higher order charge distribution, that work efficiently with the discretized fields in PIC codes, can be computed by convolving an existing charge distribution with a box function with spatial extent equivalent to a cell in the PIC code [27]

$$\rho^{(i+1)}(\vec{r}) = \rho^{(i)}(\vec{r}) \otimes \Pi(\vec{r}) \tag{3}$$

with $\rho^{(i)}(\vec{r})$ being the charge distribution of order $i$, and $\Pi(\vec{r})$ being the box function. Starting with a delta-distribution as a zeroth-order distribution $\rho^0 = \delta(\vec{r})$, higher order shapes can be derived (see sec. 3.3).

3.2. Form factors for arbitrary particle distributions

In order to take into account the charge distribution of a single macro particle, Eq. 1 needs to include an integration over the charge distribution analogous to the summation over all particles in Eq. 2.

$$\frac{d^2 I}{d\Omega d\omega} = \frac{1}{4\pi^3 \varepsilon_0 c} \left| \int dV \rho(\vec{r}) \int_{-\infty}^{+\infty} A' \cdot \chi d\tau \right|^2 \tag{4}$$

Without loss of generality, we assume that the observation direction is parallel to the $x$-axis of the coordinate system $\vec{r} = \hat{x} \cdot \vec{r}$. Furthermore, the charge distribution $\rho(\vec{r})$ can be assumed to be located around the position $\vec{r}_0 = (x_0, y_0, z_0)$. This allows integrating $\rho = \rho(x)\rho(y)\rho(z)$ over the other two axes spatially thus reducing the spatial integration to:

$$\int_{-\infty}^{+\infty} dx \int_{-\infty}^{+\infty} dy \int_{-\infty}^{+\infty} dz = \int_{-\infty}^{+\infty} dx e^{i(\vec{k} \cdot \vec{r} - \omega t)} \chi \tag{5} = e^{i\omega(\vec{k} \cdot \vec{r}_0)} \cdot \mathcal{F} [\rho(x - x_0)] \tag{6}$$

with $\mathcal{F} [\rho]$ being the Fourier transform of the charge distribution. For a point like charge distribution, $\rho(\vec{r}) = \delta(\vec{r} - \vec{r}_0)$, one ends up with Eq. 1. Since the entire charge is located in one point, the emitted radiation is completely coherent (Fig. 1).

For higher order charge distributions, the additional factor from the Fourier transform leads to vanishing energies at high frequencies and any incoherent radiation is neglected (Fig. 1). As an example, the Fourier transform of the CIC particle shape with spatial extent $\Delta$ leads to $\mathcal{F} (\omega) = \Delta/c \cdot \frac{\sin(\omega\Delta/2c)}{\omega\Delta/2c}$, which results in vanishing intensities for frequencies $\omega \gg 2c/\Delta$, while for $0 \leq \omega < 2c/\Delta$, the radiation is similar to a point like charge distribution. Such particles would not radiate at frequencies above $\omega \gg c/\Delta$. Obviously, this is physically not correct. In order to overcome this numerical artifact, the discrete nature of the electrons associated with a macro particle needs to be taken into account.

If the macro particle represents $N$ electrons $\rho(\vec{r}) = \sum_{k=1}^{N} q_e \delta(\vec{r} - \vec{r}_k)$, Eq. 2 simplifies to

$$\frac{d^2 I}{d\Omega d\omega} = \frac{q_e^2}{16\pi^3 \varepsilon_0 c} \left| \int_{-\infty}^{+\infty} \hat{A} \cdot \hat{x} \sum_{k=1}^{N} \tilde{A}_k \cdot \hat{r}_k d\tau \right|^2 \tag{7}$$

with $\tilde{A}_k = e^{i\omega(\vec{k} \cdot \vec{r}_0)/c}$ being the phase of a central position $\vec{r}_0$ of the particle distribution and $\tilde{A}_k = e^{i\omega(\vec{k} \cdot \vec{r}_0)/c}$ being the additional phase correction with the relative
position $\hat{r}_k(t) = \hat{r}_k(t) - \hat{r}_0(t)$. Since a PIC code assumes the relative position to be a time constant, one can separate the sum over all phase corrections and define a form factor $F^2$.

$$F^2(\omega) = \left| \sum_{k=1}^{N} e^{i\omega \hat{r}_k} \right|^2,$$  \hspace{1cm} (8)

This allows to simplify Eq. 7 by separating the dynamic component of the macro particle motion from its static charge distribution.

$$\frac{d^2 I}{d \Omega d \omega} = \frac{q^2}{16\pi^2 \epsilon_0 c} \int_{-\infty}^{\infty} A \cdot \hat{x} \, dt \cdot F^2(\omega) \quad \text{(9)}$$

Since the exact distribution of electrons in a plasma is unknown, Eq. 8 cannot be evaluated exactly. A probability distribution function $\psi(\hat{r}_k)$ of a single electron with index $k$ can be assumed to be proportional to the continuous charge distribution of a macro particle used in the PIC model $\psi(\hat{r}_k) \sim \rho(\hat{r})$. The probability distribution function of all $N$ electrons modeled by a macro particle is the product of all individual distributions $\psi_N(\hat{r}_1, \hat{r}_2, \ldots, \hat{r}_N) = \prod_{k=1}^{N} \psi(\hat{r}_k)$. This combined probability density allows to define a form factor $F^2(\omega)$ by averaging over all possible electron positions associated with a macro particle. Without loss of generality, $\hat{n} = \hat{z}$ can be assumed. The average form factor can thus be computed by an $N$-dimensional integral.

$$F^2(\omega) := \int_{-\infty}^{\infty} dx_1 \cdots \int_{-\infty}^{\infty} dx_N \rho(x_1, \ldots, x_N) \left| \sum_{k=1}^{N} e^{i\omega \hat{r}_k} \right|^2$$

Integration over all particle positions yields the solution.

$$F^2(\omega) = N + \left( N^2 - N \right) \int_{-\infty}^{\infty} d\chi \rho(x)e^{i\omega x} \quad \text{(10)}$$

$$F^2(\omega) = N + \left( N^2 - N \right) \cdot (F(\rho(x)))^2 \quad \text{(11)}$$

$$F^2(\omega) = N + \left( N^2 - N \right) \cdot \left( \frac{1}{\Delta} \cdot \frac{1}{\sqrt{\pi}} \cdot \int_{-\infty}^{\infty} e^{-\frac{x^2}{\Delta^2}} d\chi \right)^2 \quad \text{(12)}$$

where the first summand in Eq. 12 represents the incoherent and the second summand the coherent radiation of the $N$ electrons.

This equation was derived in [31] in the context of accelerator beam diagnostics for determining the bunch duration by measuring the coherent radiation cutoff (e.g. experimentally used in [32–35]). To the best knowledge of the authors, this is the first application of these form factors on macro particles in PIC simulations. In contrast to these previous applications, in PIC simulations both the coherent and the incoherent regime are equally important and of interest as discussed in detail in section 4.

3.3. Integrating form factors in PIC codes

In PIC simulations, the number of electrons represented by a macro particle (the so-called weighting) can vary for each macro particle. In order to evaluate Eq. 2 numerically, the following equation needs to be solved.

$$\frac{d^2 I}{d \Omega d \omega} = \frac{\Delta t}{16\pi^2 \epsilon_0 c} \sum_{j=0}^{N_j} \sum_{k=1}^{N_k} F_k(\omega) : \hat{A}_{jk} \cdot \chi_{jk}$$

with $F_k(\omega)$ being the square root of the form factor of the used particle shape at frequency $\omega$ according to the weighting of macro particle $k$. The index $j$ used in the radiation amplitude $\hat{A}_{jk}$ and the complex phase $\chi_{jk}$ of macro particle $k$ indicate the value at time $t = j \cdot \Delta t$.

The most memory-efficient approach to solving this equation within the particle-in-cell framework is to evaluate the inner sum for each time step. This requires applying the form factor for each particle before summation. If memory is not a limitation, the form factors can be applied after the time integration to each particle in a post-processing manner. This is however only technically feasible for a small number of test particles, not for billions of macro particles commonly used in simulations. Applying the form factor in-situ during the inner summation thus allows handling billions of macro particles.

The common macro particle shapes in PIC codes are cloud-in-cell (CIC), triangular-shaped density cloud (TSC) and quadratic-spline density shape (QSC) [27]. Their shape and associated form factor $F^2$ are listed in table 1, with $\Pi(x)$ being the rectangular function of width $\Delta$. Due to the convolution theorem, the form factors of these shapes is a higher power of the form factor of the CIC shape. They all contain side lobes due to the finite cut-off of the charge distribution. A physical more realistic distribution would be a Gaussian charge.

| name | $\rho(x)$ in PIC codes | $F^2(\omega)$ |
|------|------------------------|----------------|
| CIC  | $\Pi(x)$               | $\left( \frac{1}{\Delta} \cdot \frac{1}{\sqrt{\pi}} \cdot \int_{-\infty}^{\infty} e^{-\frac{x^2}{\Delta^2}} d\chi \right)^2$ |
| TSC  | $\Pi(x) \otimes \Pi(x) = \Delta(x)$ | $\left( \frac{1}{\Delta} \cdot \frac{1}{\sqrt{\pi}} \cdot \int_{-\infty}^{\infty} e^{-\frac{x^2}{\Delta^2}} d\chi \right)^2$ |
| QSC  | $\Lambda(x) \otimes \Pi(x)$ | $\left( \frac{1}{\Delta} \cdot \frac{1}{\sqrt{\pi}} \cdot \int_{-\infty}^{\infty} e^{-\frac{x^2}{\Delta^2}} d\chi \right)^3$ |
| Gauss| $\exp \left(-\frac{x^2}{\Delta^2}\right)$ | $\left( \frac{1}{\Delta} \cdot \frac{1}{\sqrt{\pi}} \cdot \int_{-\infty}^{\infty} e^{-\frac{x^2}{\Delta^2}} d\chi \right) - \frac{x^2}{\Delta^2}$ |
distribution, also listed in table 1. It lacks the side lobes in the transition between coherent and incoherent radiation and can thus be considered more suited for exploring radiation signatures where numerical peaks should be avoided. For implementation in radiation damping algorithms, the self consistent treatment with equivalent shapes as used in the PIC algorithm should be used.

4. Coherent and incoherent radiation from laser wakefield acceleration

In this section, an LWFA simulation performed with the PIC code PIConGPU [36, 37] is presented to illustrate on a single electron trajectory that both coherent and incoherent radiation is emitted by the same macro particle and that not taking care of the scaling of both regimes leads to overestimation of the incoherent radiation. In this simulation, a plasma cavity is created into which electrons are injected via self-injection. Fig. 2 illustrate the plasma dynamic during injection and the trajectory of the sample macro particle for the entire simulation time in a co-moving frame. During its entire dynamic, the electron emits radiation at various frequencies (Fig. 3). These are initially coherent, e.g. the Thomson scattering of laser light, but become incoherent during the betatron radiation in the x-ray frequency range. Fig. 3 illustrate the various scalings of assuming fully coherent, fully incoherent and a, with a form factor adjusted, spectra. Not correcting the spectra would lead to an overestimation of the energy emitted at high frequencies. The form factor allows a quantitative correct prediction.

Due to the 0.13 billion macro particles considered in this simulation, a post-processing application of the form factor would technically be not feasible.

5. Summary

In this paper, we derived form factors for commonly used macro particle shapes that allow quantifying coherent and incoherent radiation in synthetic diagnostics efficiently and discussed an implementation in PIC codes. On the example of an LWFA simulation, the need for this more thorough treatment of the discrete nature of the electrons represented by macro particles in PIC codes was demonstrated.

Using these form factors in synthetic radiation diagnostics not only paves the way towards quantitative radiation predictions from PIC codes that allow direct comparison with experiments, but also allows to predict the brightness of plasma based light sources such as betatron radiation or high harmonic generation.
