In this study, the dynamic stability derivatives of an aircraft model are calculated using CFD for the forced-pitch oscillation. The time-spectral, or reduced-frequency, method has been developed for RANS simulations on unstructured grids. It achieves faster computations than the time-marching method for periodically unsteady flows. The efficiency and accuracy of the method are first validated through comparisons with the transonic experimental data of a pitching LANN wing. Next, the longitudinal dynamic-stability derivatives of a simplified aircraft model are calculated. Dependency of the damping-in-pitch and oscillatory longitudinal stability on the Mach number agreed reasonably well with the experimental results. Both the instantaneous flow field and frequency characteristics obtained directly from the time-spectral results are discussed to determine the effect of Mach number on the stability derivatives.

Key Words: CFD, Unstructured Grids, Aircraft Dynamic Stability

1. Introduction

The calculation of dynamic stability derivatives is an indispensable factor in considering the stability and maneuverability of an aircraft. Attempts to obtain the dynamic derivatives through wind tunnel testing have a long history, and in many cases, two primary methods are the free oscillation method for measuring the displacement of motion at a limited degree-of-freedom of motion, and the forced oscillation method for measuring the force and moment acting on the model under a prescribed motion.1–3) Meanwhile, with the improvement of CFD analysis capability, the prediction of dynamic stability derivatives using CFD is becoming a realistic approach.4–6) It is expected that CFD plays an important role in advancing integrated design based on correct flight dynamic characteristics from the initial stage of design of advanced aircraft such as supersonic transport or blended wing-body aircraft, as well as today’s matured commercial aircraft configuration. In Japan, JAXA renewed a dynamic stability test apparatus by introducing the forced excitation method in 20042) for the purpose of acquiring the transonic speed characteristics of the space transport HOPE-X, and the measurement accuracy was verified using the Standard Dynamics Model (SDM). As a corresponding CFD analysis for the SDM, unsteady calculation using JAXA’s CFD code FaSTAR has been carried out and reported recently.6)

The time-marching (TM) method in CFD can be used for any unsteady problem, but special care to maintain the same time accuracy is necessary to ensure the reliability of the solution. Although the authors have calculated dynamic coupled oscillation problems such as wing rock or flutter boundary prediction,7) the TM method with an appropriate time step requires a calculation time several tens of times that of the steady-flow method. In the small amplitude oscillation test for aircraft dynamic stability analysis, however, the flow field is expected to be similar to the harmonic vibration solution around the stationary solution. It is important to be able to efficiently perform a large number of analyses of such flows during aircraft design. The objective of this research is to develop a time spectral (TS) method, instead of using the TM method, that enables unsteady solutions to be obtained periodically, with an emphasis on predicting the dynamic stability derivatives of the aircraft.

The TS method was used in CFD for the first time by Hall et al.8) to analyze the vibrational flow of a two-dimensional turbine blade cascade. It is also called the nonlinear frequency domain method or harmonic balance method.9,10) New governing equations are derived for the coefficients of the time Fourier series expansion of the original unknown variables, and the solutions (expansion coefficients) are obtained as a converged solution with respect to the pseudo-time. The TS method was applied to the aircraft stability problem by Murman,5) and the dynamic derivatives of SDM were calculated using inviscid flow analysis on adaptively refined Cartesian grids. Moreover, Da Ronch et al.10) also developed a TS method for RANS analysis on multi-block structured grids to evaluate the dynamic stability of large-sized passenger aircraft.

In order to enhance the efficiency and versatility of the TS method for simultaneous acquisition of static/dynamic stability derivatives, in this paper we introduce a fully implicit method for fast convergence of periodic unsteady RANS solutions on unstructured grids in pseudo-time. To the authors’ knowledge, this is the first report on using the TS method for high-Reynolds number flows on unstructured grids handling arbitrary aircraft configurations. The transport
equation for the turbulence model is also solved using the TS method. It is an extension of our previous report using structured grids,\(^1\)\(^1\) in which we showed simple implementations using existing implicit TM code and succeeded in reducing the computation time by a factor of 15 for periodic flows. The procedure for the acquisition of stability derivatives is made more efficient using an automatic grid generator, HexaGrid, developed by JAXA.\(^1\)\(^2\)

2. Numerical Algorithm

2.1. Governing equations in the time domain

The governing equations are compressible Navier-Stokes equations with a moving boundary. The time-dependent equation in the integral form for the time-marching method is expressed as follows,

\[ \frac{\partial}{\partial t} \int_{\Omega} QdV + \oint_{\partial\Omega(t)} F_n dS = 0 \]  

where, \( Q \) is a conservative variable vector, \( \Omega \) is the control volume (CV) around each node (vertex) of the grids, and \( F_n \) is a flux vector in the normal direction to the control volume (CV) boundary \( \partial\Omega(t) \). In this study, the computational grids rotate rigidly, and then \( \Omega \) is constant with time while the normal vector of the CV boundary \( \partial\Omega(t) \) varies with time. We also use the Spalart-Allmaras turbulence model to calculate the eddy viscosity. More specifically, a model that considers quadratic constitutive relation (QCR)\(^1\)\(^3\) is used as it is known to be effective for suppressing excessive flow separation near the wing-body conjunction. The governing equation for the model is written in the same form as Eq. (1), with a source term added on the right-hand side.

2.2. Spatial discretization

A finite volume method is used for the spatial discretization. In Eq. (1), the CV average of the conservative variable in the first term is redefined as \( \bar{Q} \), and the second term (and the source term for the turbulence model) is expressed as \( R(Q) \) to obtain the following semi-discretized equation,

\[ \frac{\partial (V \cdot \bar{Q})}{\partial t} + R(Q) = 0 \]  

where, \( V \) is the volume of CV. Since all of the computational grids move rigidly in this study to represent the motion of the object, the volume does not change over time. The high-resolution upwind scheme SHUS is used for the numerical flux of the convective term and second-order accuracy in space is achieved by linear reconstruction of the primitive variables using Venkatakrishnan’s slope limiter. Discretization of the viscous term corresponds to the second-order central scheme.

2.3. Time spectral (TS) method

The time spectral method is described below. If the solution vector \( Q \) and residual \( R(Q) \) are the periodic function of time, their finite Fourier series expansions are given by the following equation,

\[ Q(x, n\Delta t) = \sum_{k=-(N-1)/2}^{(N-1)/2} \hat{Q}_k e^{-ik\omega n\Delta t} \]  

\[ R(x, n\Delta t) = \sum_{k=-(N-1)/2}^{(N-1)/2} \hat{R}_k e^{-ik\omega n\Delta t} \]

where, \( \hat{Q}_k \) and \( \hat{R}_k \) are the complex Fourier coefficients, and \( i \) is an imaginary unit. \( N \) is the number of samples in one cycle \( T \) (i.e., period of forced oscillation) and defined as \( N = T/\Delta t \) with the sample interval time \( \Delta t \). \( N \) is an odd number in this study. The equation \( \omega = 2\pi/(N\Delta t) \) is the angular frequency and \( n \) denotes the data number \( n = -(N-1)/2, \ldots, 0, \ldots, (N-1)/2 \) in one cycle. In this study, \( n = 0 \) at the forced oscillation phase \( \phi = 0 \) of the object, and the range \(-\pi < \phi < \pi \) is equally divided by \( N \). Since \( Q \) and \( R \) are real numbers, the Fourier coefficient of the negative wave number \( k \) is a complex conjugate of a corresponding positive wave number and the Fourier series is truncated by the \((N-1)/2\)-th harmonics of the frequency \( \omega \) in Eqs. (3) and (4). Substituting these into Eq. (2) and using the orthogonality of the Fourier mode, the following equation is obtained.

\[ V \cdot i\omega \hat{\dot{Q}}_k + \hat{\dot{R}}_k = 0 \]  

A pseudo-time term \( V \cdot d\hat{Q}_k/d\tau \) is actually added to the left-hand side of Eq. (5) and Fourier coefficients are obtained as a steady solution. It could be solved explicitly with respect to \( \tau \) with the use of Fourier/inverse Fourier transformations in the solution process. But it is difficult to directly apply the implicit time method since \( \hat{\dot{R}}_k \) is a function of \( Q \) through \( R \), and thus both \( Q \) and \( \hat{\dot{Q}}_k \) appear in Eq. (5). Therefore, Eq. (5) is changed to include time-domain variables simply by substituting the discrete Fourier transform:

\[ \hat{\dot{Q}}_k(x) = \frac{1}{N} \sum_{n=-(N-1)/2}^{(N-1)/2} Q(x, n\Delta t)e^{-ik\omega n\Delta t} \]  

\[ \hat{\dot{R}}_k(x) = \frac{1}{N} \sum_{n=-(N-1)/2}^{(N-1)/2} R(x, n\Delta t)e^{-ik\omega n\Delta t} \]

By arranging this into real and imaginary parts, the following equations are finally obtained,

\[ V \frac{dQ_n}{d\tau} + V\omega \sum_{j=-(N-1)/2}^{(N-1)/2} c_{nj} Q_j + R_n = 0 \]  

where, \( Q_n = Q(x, n\Delta t) \). The coefficient \( c_{nj} \) is defined below.

\[ c_{nj} = \begin{cases} \frac{(-1)^{n-j}}{2} \cot \left( \frac{\pi(n-j)}{N} \right) & (n \neq j) \\ 0 & (n = j) \end{cases} \]

An implicit method for the pseudo-time is written as

\[ \left( \frac{1}{\Delta t} V + \frac{\partial R}{\partial Q} \right) \Delta Q_n + V\omega \sum_j c_{nj} \Delta Q_j = -\left( V\omega \sum_j c_{nj} (Q_j + R_n) \right) \]
The system of equation for $\Delta Q_n$ of all data numbers (i.e., all sample solutions in one cycle) is solved using the symmetric Gauss-Seidel method. By setting the initial value of $\Delta Q_n$ to 0, and shifting the second term on the left-hand side to the right-hand side (diagonal term $c_{nj} = 0$), it is solved using the forward/backward substitution below.

Forward:

$$\Delta Q_n^* = \left( \frac{I}{\Delta t} V + \frac{\partial R}{\partial Q} \right)^{-1} \left[ -\left( V_0 \sum_{j=1}^n c_{nj} Q_j + R_n \right) - V_0 \sum_{j,n} c_{nj} \Delta Q_j^* \right]$$

(11)

Backward:

$$\Delta Q_n = \Delta Q^* - \left( \frac{I}{\Delta t} V + \frac{\partial R}{\partial Q} \right)^{-1} \left[ V_0 \sum_{j,n} c_{nj} \Delta Q_j \right]$$

(12)

For inverting the (huge) coefficient matrix of the diagonal term, the same Matrix-free Gauss-Seidel method\(\textsuperscript{14}\) as the TM method is used.

3. Calculation Method for Dynamic Stability Derivatives

Dynamic stability derivatives in the longitudinal motion are calculated as follows. Assuming that the pitching moment coefficient $C_m$ at a certain Mach number is a function of the angle-of-attack $\alpha$, pitch angular velocity $q = \dot{\theta}$, and their time derivatives $\dot{\alpha}$ and $\dot{q}$, the linearized equation of motion of an aircraft about the equilibrium state is written as follows,

$$I_{yy} \ddot{\theta} = \frac{\rho U^2 S \bar{c}}{2} \left( C_{m0} + C_{m1} \Delta \alpha + \frac{l}{U} C_{m2} \alpha + \frac{l}{U} C_{m3} q + \left( \frac{l}{U} \right)^2 C_{m4} \dot{q} \right)$$

(13)

where, $I_{yy}$ is the moment of inertia around the pitch axis, $\rho U^2 / 2$ is the dynamic pressure, and $l$ is the reference length, which is one-half the size of the mean aerodynamic chord (MAC) $\bar{c}$. The non-dimensional stability derivatives are defined as follows,

$$C_{m0} = \frac{\partial C_m}{\partial \alpha}, \quad C_{m1} = \frac{\partial C_m}{\partial \dot{\theta}} \left( \frac{\bar{c}}{2U} \right), \quad C_{m2} = \frac{\partial C_m}{\partial \alpha^2} \left( \frac{\bar{c}}{2U} \right),$$

$$C_{m3} = \frac{\partial C_m}{\partial \dot{\theta} q} \left( \frac{\bar{c}}{2U} \right), \quad C_{m4} = \frac{\partial C_m}{\partial \dot{\theta} \dot{q}} \left( \frac{\bar{c}}{2U} \right)$$

(14)

By setting $\alpha = \theta$ and $\Delta \theta = \Delta \alpha = \alpha_0 \sin(\omega t)$, the stability derivatives on the right-hand side of Eq. (13) are expressed as,

$$\Delta C_m = C_m - C_{m0} = \alpha_0 k (C_{m0} + C_{m1}) \cos(\omega t) + \alpha_0 (C_{m2} - k^2 C_{m0}) \sin(\omega t)$$

(15)

where, $k = \alpha \bar{c} / 2U$ is a reduced (non-dimensional) frequency. The physical meaning of each term in Eq. (15) can be seen by assuming the motion around a zero angle-of-attack:

$$\Delta C_m = \frac{\dot{\bar{c}}}{2U} (C_{m0} + C_{m1}) \dot{\theta} + (C_{m2} - k^2 C_{m0}) \theta$$

(16)

Then, Eq. (13) can be expressed as,

$$I_{yy} \ddot{\theta} = \frac{\bar{M}}{2U} (C_{m0} + C_{m1}) \dot{\theta} - \bar{M} (C_{m2} - k^2 C_{m1}) \theta = 0$$

(17)

where, $\bar{M} = \rho U^2 S \bar{c} / 2$. In the above equation, the second term on the left-hand side represents the damping aerodynamic moment, and the third term represents the restoring moment. The term $C_{m0} + C_{m1}$ is referred to as the damping in pitch, while the term $C_{m2} - k^2 C_{m1}$ is referred to as the oscillatory longitudinal stability. They are also called the out-of-phase component and in-phase component\(\textsuperscript{14}\) to the reference (forced) oscillation, respectively. In the TS method, these derivatives are obtained as the real and imaginary parts of the first-harmonic Fourier coefficients of $C_m$.

The dynamic derivative $C_m$ is separately obtained using the forced-heaving motion of an aircraft in the following way, although results are not included in this paper due to the lack of reference experiments. In the periodic heaving motion expressed as $\zeta = (h_0 \cdot I \sin(\omega t))$, where $h_0$ is the non-dimensional amplitude normalized by $l = \bar{c}/2$, the variation of $C_m$ in time is expressed as

$$\Delta C_m = C_{m0} \Delta \alpha + \frac{l}{U} C_{m1} \dot{\alpha}$$

$$= \frac{h_0 \alpha_0}{U} C_{m0} \cos(\omega t) - \frac{h_0^2 \alpha_0^2}{U^2} C_{m0} \sin(\omega t)$$

$$= h_0 k C_{m0} \cos(\omega t) - h_0 k^2 C_{m0} \sin(\omega t)$$

(18)

since $\Delta \alpha = \bar{c} / U$, $\dot{\alpha} = \bar{c} / U$, and $q = \dot{q} = 0$ in a similar formula found in Eq. (13). $C_{m1}$ is obtained as the imaginary part of the first-harmonic Fourier coefficients of $C_m$ using the heaving motion.

4. Results and Discussions

Simulation results for two objects are shown in this section: one is the forced-pitch oscillation of a supercritical wing alone to compare unsteady pressure distribution with the experiment, and the other is the pitching oscillation for a simplified whole aircraft model to compare the stability derivatives at a wide range of Mach numbers. The pitching motions in both cases are described as follows,

$$\alpha(t) = \alpha_m + \alpha_0 \sin(\omega t)$$

(19)

where, $\alpha_m$ and $\alpha_0$ denote the mean angle-of-attack and the amplitude of the forced oscillation, respectively.
All computational grids are generated using the HexaGrid,\textsuperscript{12} developed by JAXA.

4.1. LANN wing

In this subsection, simulation results for the forced-pitch oscillation of a practical transonic wing called Lockheed-Georgia, Air force, NASA Langley, NLR (LANN) model\textsuperscript{15,16} are shown. The wing aspect ratio is 7.92, the sweepback angle of 25\% chord lines is 25°, and the taper ratio is 0.4. The airfoil is a supercritical wing with 12\% thickness. The maximum installation angle at the root chord is linearly twisted down toward the tip and the twist angle is 4.8°.

Figure 1 shows the wing shape and the computational grids in a symmetrical plane. The number of total grid points is 816,728.

The forced-pitch oscillation is performed around the axis of the 62\% root chord location. The freestream Mach number is 0.82, which was intensively examined in the wind tunnel experiment. Calculation conditions for the parameters in Eq. (19) and the reduced frequency $k$ are summarized in Table 1. The Reynolds number $Re = 5.43 \times 10^6$ in the wind tunnel is based on a MAC of 0.268 [m].

Table 1. Flow conditions for the LANN wing.

| $M_\infty$ | $\alpha_m$ [deg] | $\alpha_0$ [deg] | $k$ | $Re$ |
|-----------|-----------------|-----------------|-----|------|
| 0.82      | 0.6             | 0.5             | 0.102 | $5.43 \times 10^6$ |

Both TS and TM simulations were run in this case to validate the TS method developed. For the TM method, the wing started oscillating from the steady flow at $\alpha_m$ angle-of-attack and the calculation continued until four cycles were reached to obtain the periodic solution. For the TS method, the number of sample points $N$ in one cycle was set to five, which corresponds to taking the Fourier modes up to the second harmonics.

Figure 2 shows the pressure contours for the steady flow. Figures 3(a) and (b) show steady-state pressure coefficient ($C_p$) plots at 20\% and 47.5\% spanwise stations, respectively. The two-step change on the upper surface in Fig. 3(a) corresponds the $\lambda$-shaped shock waves in Fig. 2. The two shock waves near the root merge to a single shock wave towards the wingtip and a single step of $C_p$ is observed in Fig. 3(b). Figures 3(c)–(f) show the unsteady results resulting from the pitching motion, which are the real and imaginary parts of the Fourier coefficients’ first harmonic component of the $C_p$ obtained as below.

$$C_p(t) = \sum_{k=-\infty}^{\infty} \hat{C}_p^k e^{ikt}$$

$$= \hat{C}_p^0 + 2 \Re(e^{ikt}) - 2 \Im(e^{ikt}) + \cdots$$

$$\quad\quad (20)$$
The values in Figs. 3(c)–(f) are normalized by the amplitude \(\alpha_0\) in radian. The TS and TM results agree with each other in all plots. Multiple peaks at 20% station and single peak at 47.5% station on the upper surface are the result of the shock-wave motions discussed above. Agreement with the experiment is also good, especially near the mid-span station. The absolute value (amplitude) of the second Fourier mode of the pitching-moment coefficient is about 10% of that of the first mode. Next, it was confirmed that the sample number of 5 is sufficient for small-amplitude, forced oscillation used in this study.

For the TM method, the number of time steps set for one cycle is 5,000 and the Newton iteration per step to eliminate unsteady residual is 5, based on a preliminary study. For the TS method, \(N = 5\) sampled solutions converge to periodic unsteady solutions in less than 4,000 steps. Computation using the TS method was about 15 times faster than the TM method. In our implementation, the ‘strong boundary condition’ for the wall was not optimum for the implicit TS method, though it worked well for the TM method. Using the TS method, all residuals, including boundary nodes, should be expressed in the delta form, as done in Eqs. (11) and (12). Accordingly, the weak boundary condition for finite volume was better suited, allowing for larger pseudo-time steps and faster convergence.

4.2 Aircraft model with 45° sweptback wings

Experimental data of dynamic stability derivatives obtained using forced-pitch and yaw oscillations of a simple aircraft configuration were reported in Bielat and Wiley.\(^2\) The focus of this study is longitudinal characteristics. The airfoil of a NACA65A005 is commonly used for the main wing and horizontal/vertical tail wings. The sweptback angle at one-quarter chord is also common at 45° for all wings. The aspect ratios of the main wing, horizontal tail and vertical tail are 4, 3.5, and 1.23, respectively, and the taper ratios are 0.2, 0.4, and 0.4, respectively. The fuselage consists of an ogive nose and the following circular-cylinder. The model plan view is shown in Fig. 4.

The forced-pitch oscillation described in Eq. (19) is performed at a MAC of approximately 25% of the main wing. Calculation conditions are summarized in Table 2. The Reynolds number of the wind tunnel experiment is \(Re = 1.1 \times 10^6\) based on a MAC of 0.175 [m].

Computational grids with different resolutions were prepared. The coarse grid consists of 2,276,435 points and the fine grid shown in Fig. 5 consists of 5,024,987 points. All of the Mach numbers in Table 2 are simulated on the coarse grid, and three cases at \(M_{\infty} = 0.95, 0.98\) and 1.03 are calculated on the fine grid.

The TM simulation was carried out again only at \(M_{\infty} = 0.95\) on the coarse grid to compare the results obtained using the TS method. The calculation procedure for the TM method is the same as that described in Subsection 4.1, and the number of sample points \(N\) in one cycle for the TS method is also five. Figure 6 shows the dynamic dependence of the normal force coefficient \(C_N\) and the pitching moment coefficient \(C_m\) on the angle-of-attack \(\alpha\) at \(M_{\infty} = 0.95\). Almost the same solutions are obtained with a shorter calculation time using the TS method. The hysteresis of \(C_N\) is hardly visible compared to that of \(C_m\). The profile of \(C_m\) is close to an inclined ellipse, which shows that the influence of the third or higher harmonic components neglected by \(N = 5\) is small.

Figures 7(a) and (b) respectively show the responses of dynamic \(C_N - \alpha\) and \(C_m - \alpha\) at \(M_{\infty} = 0.95\). The TM simulation was carried out again only at \(M_{\infty} = 0.95\) on the coarse grid to compare the results obtained using the TS method. The calculation procedure for the TM method is the same as that described in Subsection 4.1, and the number of sample points \(N\) in one cycle for the TS method is also five. Figure 6 shows the dynamic dependence of the normal force coefficient \(C_N\) and the pitching moment coefficient \(C_m\) on the angle-of-attack \(\alpha\) at \(M_{\infty} = 0.95\). Almost the same solutions are obtained with a shorter calculation time using the TS method. The hysteresis of \(C_N\) is hardly visible compared to that of \(C_m\). The profile of \(C_m\) is close to an inclined ellipse, which shows that the influence of the third or higher harmonic components neglected by \(N = 5\) is small.

| \(M_{\infty}\) | \(\alpha_m\) [deg] | \(\alpha_0\) [deg] | \(k\) | \(Re\)  |
|-----------|-----------------|-----------------|-----|--------|
| 0.7, 0.9, 0.95, 0.98, 1.03, 1.15 | 0 | 2 | 0.024 | 1.1 \times 10^6 |

shown. As for the oscillatory longitudinal stability, the ten-
the experimental results. We further investigated the e
isotropic tetrahedron elements. No major di
seen in these tests. Considering the variance for each wind
on the results. In the latter case, simulations were run on
$M_{\infty}$ increases, and the difference between pitch-up and pitch-down
at the same angle-of-attack becomes small (i.e., hysteresis decreases). We note that the absolute value (i.e., amplitude) of
the second Fourier mode of $C_m$ is less than 3.5% of the first
mode for all cases, thus validating the solution sample num-
icant quantitative di
of the ellipse-like history in Fig. 7(b) transits counterclock-
rate of abrupt change indicating a decrease in dynamic stability near $M_{\infty} = 1$ is clearly shown. As for the oscillatory longitudinal stability, the ten-
dency of gradual increase across $M_{\infty} = 1$ is reproduced. The results on the fine grid at $M_{\infty} = 0.95$, 0.98, and 1.03
are also shown in Fig. 8, showing the effect of grid resolu-
tion. The stability derivatives values predicted using the fine grid are similar to those obtained using the coarse grid. The Mach number of abrupt change for pitch damping is again between $M_{\infty} = 0.95$ and 0.98, which is slightly lower than the experimental results. We further investigated the effect of the outer boundary location and the effect of viscosity on the results. In the latter case, simulations were run on
completely different unstructured grids composed of iso-
tropic tetrahedron elements. No major differences were ob-
served in these tests. Considering the variance for each wind
tunnel test observed in the dynamic test of SDM1,13) and simi-
larly quantitative differences found in another study,5) we re-
gard our results as reasonably accurate.

The characteristic change in stability derivatives shown
above can be explained by the Mach number dependencies in
Fig. 7(b). First, the increase in the negative slope of $C_m$
with the increasing Mach number corresponds to the increase
in (oscillatory) longitudinal stability in Fig. 8. Next, since all of
the ellipse-like history in Fig. 7(b) transits counterclock-
wise, the area enclosed denotes the kinetic energy of the air-
craft lost due to fluid flow during one cycle. The decrease in
the area as the Mach number increases then reflects the de-
crease in pitch damping shown in Fig. 8. Figure 9 addition-
ally supports this explanation, which shows the input (i.e.,
forced sinusoidal pitching)-to-output (i.e., response of $C_m$
relation. In the two ordinates, the amplitude ratio denotes
$|\dot{C}_m|/\alpha_0$ and the phase difference denotes $\arg(\dot{C}_m)$. They re-
spectively correspond to the magnitude of the oscillatory lon-
gitudinal stability and pitch damping. The plots show the
same Mach number dependency as Fig. 8.

The flows for $M_{\infty} = 0.95$ and 1.03 showing significant
differences in damping are compared. Figures 10(a)–(d)
show instantaneous surface pressure distributions at the
phase of $\phi = 0$ and $2\pi/5$, which are respectively $n = 0$
and 1 in terms of the data number among $N = 5$ samples
in the cycle. The pressure contours in the MAC spanwise
section are also shown. In the case of $M_{\infty} = 0.95$ in
Figs. 10(a) and (b), the shock wave on the main wing is al-
most perpendicular to the freestream, and is located at a
MAC of approximately 60% to 70%. In the case of
$M_{\infty} = 1.03$ in Figs. 10(c) and (d), the shock wave is parallel

©2019 JSASS
296
to the trailing-edge near 90% MAC. The real and imaginary parts of the first harmonic component of unsteady $C_p$ at the MAC section are shown in Figs. 11(a)–(d). Figures 11(a) and (b) are those at $M_\infty = 0.95$ on the main wing and tail wing, respectively. Figures 11(c) and (d) are the same sets at $M_\infty = 1.03$. Figures 12(a) and (b) further show the surface distributions of the first harmonics magnitude, $|\tilde{C}_{p1}|$. In Figs. 11(a) and (c), the imaginary part, or the in-phase component of $C_p$, is dominant on the main wing at both Mach numbers. Another important feature is a clear peak in the imaginary part from 60% to 75% chord in Fig. 11(a), in contrast to almost flat distribution in Fig. 11(c). These features are also seen in the surface plots in Figs. 12(a) and (b). The region of large amplitude of unsteady $C_p$ exists in Fig. 12(a) on the main wing from the mid-span to tip region, which is due to the shock-wave motion. While in Fig. 12(b), the amplitude on the main wing is almost uniform except for the leading-edge and trailing-edge. As for the horizontal tail wing, the real and imaginary parts have similar amplitudes at $M_\infty = 0.95$ in Fig. 11(b), which indicates the phase difference from the forced oscillation. The imaginary part at $M_\infty = 1.03$ in Fig. 11(d) is again dominant, like the main wing. The clear peak due to the shock-wave motion over the main wing and the phase difference on the tail wing at $M_\infty = 0.95$ result in the phase difference in the $C_m$ response discussed in Figs. 7 to 9.

5. Conclusion

A time-spectral (TS) CFD method for RANS simulation on unstructured grids has been developed to efficiently analyze the periodic unsteady flow around a oscillating object. Using the conventional time-marching (TM) method, special attention is required to obtain a solution that does not depend
on the time-step size, while in the TS method, sampled solutions in one cycle are obtained as steady solutions in the pseudo-time. The method is validated through two problems: One is for predicting unsteady pressures on an oscillating transonic wing, and the other is for predicting dynamic stability derivatives of a simple whole aircraft configuration. In both cases, the TS results agreed with the TM results, doing so while requiring a computation time that is shorter by a factor of approximately 4. The dependencies of the aircraft dynamic stability on the flow Mach number were captured well, although quantitative agreement with the experiment was not sufficient. The effectiveness and accuracies of the method will be further verified for a wider range of calculation objects and calculation conditions.

Acknowledgments

This work was supported by JSPS KAKENHI Grant Number JP19K04835.

The authors wish to express their gratitude to JAXA for providing the automatic grid generator, HexaGrid.
