On the Stopping Distance and the Stopping Redundancy of Codes

Moshe Schwartz, Member, IEEE, and Alexander Vardy, Fellow, IEEE

Abstract—It is now well known that the performance of a linear code \( C \) under iterative decoding on a binary erasure channel (and other channels) is determined by the size of the smallest stopping set in the Tanner graph for \( C \). Several recent papers refer to this parameter as the stopping distance \( s \) of \( C \). This is somewhat of a misnomer since the size of the smallest stopping set in the Tanner graph for \( C \) depends on the corresponding choice of a parity-check matrix. It is easy to see that \( s \leq d \), where \( d \) is the minimum Hamming distance of \( C \), and we show that it is always possible to choose a parity-check matrix for \( C \) (with sufficiently many dependent rows) such that \( s = d \). We thus introduce a new parameter, termed the stopping redundancy of \( C \), defined as the minimum number of rows in a parity-check matrix \( H \) for \( C \) such that the corresponding stopping distance \( s(H) \) attains its largest possible value, namely \( s(H) = d \). We then derive general bounds on the stopping redundancy of linear codes. We also examine several simple ways of constructing codes from other codes, and study the effect of these constructions on the stopping redundancy. Specifically, for the family of binary Reed-Muller codes (of all orders), we prove that their stopping redundancy is at most a constant times their conventional redundancy. We show that the stopping redundancies of the binary and ternary extended Golay codes are at most 34 and 22, respectively. Finally, we provide upper and lower bounds on the stopping redundancy of MDS codes.

Index Terms—erasure channels, Golay codes, iterative decoding, linear codes, MDS codes, Reed-Muller codes, stopping sets.

I. INTRODUCTION

The recent surge of interest in the binary erasure channel (BEC) is due in large part to the fact that it is the prime example of a channel over which the performance of iterative decoding algorithms can be analyzed precisely. In particular, it was shown by Di, Proietti, Telatar, Richardson, and Urbanke [7] that the performance of an LDPC code (and, in fact, any linear code) under iterative decoding on the BEC is completely determined by certain combinatorial structures called stopping sets. A stopping set \( S \) in a code \( C \) is a subset of the variable nodes in a Tanner graph for \( C \) such that all the neighbors of \( S \) are connected to \( S \) at least twice. The size \( s \) of the smallest stopping set was termed the stopping distance of \( C \) in a number of recent papers [14], [19]. The stopping distance plays an important role in understanding the performance of a code under iterative decoding over the BEC, akin to the role played by the minimum Hamming distance \( d \) for maximum-likelihood and/or algebraic decoding. Just as one would like to maximize the minimum distance \( d \) if maximum-likelihood or algebraic decoding is to be used, so one should try to maximize the stopping distance \( s \) in the case of iterative decoding.

There is, however, an important difference between the minimum distance \( d \) and the stopping distance \( s \). While the former is a property of a code \( C \), the latter depends on the specific Tanner graph for \( C \) or, equivalently, on the specific choice of a parity-check matrix \( H \) for \( C \). In order to emphasize this, we will henceforth use \( s(H) \) to denote the stopping distance and \( d(C) \) to denote the minimum distance.

In algebraic coding theory, a parity-check matrix \( H \) for a linear code \( C \) usually has \( n - \dim(C) \) linearly independent rows. However, in the context of iterative decoding, it has been already observed in [20], [24] and other papers that adding linearly dependent rows to \( H \) can be advantageous. Certainly, this can increase the stopping distance \( s(H) \). Thus, throughout this paper, a parity-check matrix for \( C \) should be understood as any matrix \( H \) whose rows span the dual code \( C^\perp \). Then the redundancy \( r(C) \) of \( C \) may be defined as the minimum number of rows in a parity-check matrix for \( C \). Analogously, we define the stopping redundancy \( \rho(C) \) as the minimum number of rows in a parity-check matrix \( H \) for \( C \) such that \( s(H) = d(C) \). This work may be thought of as the first investigation of the trade-off between the parameters \( \rho(C) \), \( r(C) \), and \( d(C) \).

In the next section, we first show that the stopping redundancy \( \rho(C) \) is well-defined. That is, given any linear code \( C \), it is always possible to find a parity-check matrix \( H \) for \( C \) such that \( s(H) = d(C) \). In fact, the parity-check matrix consisting of all the nonzero codewords of the dual code \( C^\perp \) has this property. Hence \( \rho(C) \leq 2^{\dim(C)} - 1 \) for all binary linear codes. We then show in Section II that if \( d(C) \leq 3 \), then any parity-check matrix \( H \) for \( C \) satisfies \( s(H) = d(C) \), so \( \rho(C) = r(C) \) in this case. The main result of Section II is an extension of this simple observation to a general upper bound on the stopping redundancy of binary linear codes (Theorem 4). We also derive in Section II a general lower bound on the stopping redundancy of linear codes (Theorem 5).

In Section III, we study several simple ways of constructing codes from other codes, such as the direct-sum construction and code extension by adding an overall parity-check. We investigate the effect of these constructions on the stopping redundancy. It should be pointed out that although we have focused our discussion on binary codes in Sections II and III, most of the results therein extend straightforwardly to linear codes over an arbitrary finite field.

We continue in Section IV with an in-depth analysis of the well-known \((u, u + v)\) construction, and in particular its application in the recursive definition [17, p. 374] of binary Reed-
Muller codes. By slightly modifying this construction, we establish a strong upper bound on the stopping redundancy of Reed-Muller codes of arbitrary orders. Specifically, we prove that if \( C \) is a Reed-Muller code of length \( 2^m \) and order \( r \), then \( \rho_1(C) \leq d(C) r(C)/2 \). Thus for any constant \( d(C) \), we have an increase in redundancy by only a constant factor.

In Section V, we study the \((24,12,8)\) extended binary Golay code \( G_{24} \) and the \((12,6,6)\) extended ternary Golay code \( G_{12} \). We prove that \( \rho(G_{24}) \leq 34 \) and \( \rho(G_{12}) \leq 22 \) by providing specific parity-check matrices for these codes. We take \( G_{24} \) as a test case, and compare the performance of three different decoders: a maximum-likelihood decoder, an iterative decoder using the conventional \( 12 \times 24 \) double-circulant parity-check matrix of [17, p.65], and an iterative decoder using the \( 34 \times 24 \) parity-check matrix with maximum stopping distance. In each case, exact analytic expressions for the probability of decoding failure are derived using a computer program (see Figure 1).

In Section VI, we consider MDS codes over \( \mathbb{F}_q \) with \( q \geq 2 \). It is easy to extend the general bounds of Section II to \( q \)-ary codes. However, in Section VI we establish much better upper and lower bounds on the stopping redundancy of MDS codes. Notably, all these bounds are independent of the field size \( q \).

This paper only scratches the surface of the many interesting and important questions that arise in the investigation of the stopping redundancy. We conclude in Section VII with a brief discussion and a list of open problems.

II. General Bounds

We begin with rigorous definitions of the stopping distance and the stopping redundancy. Let \( C \) be a binary linear code and let \( H = \{h_{i,j}\} \) be a parity-check matrix for \( C \). The corresponding Tanner graph \( T \) for \( C \) is a bipartite graph with each column of \( H \) represented by a variable node and each row of \( H \) represented by a check node in such a way that the \( j \)-th variable node is connected to the \( i \)-th check node if and only if \( h_{i,j} \neq 0 \). As already mentioned, a stopping set in \( T \) is a subset \( S \) of the variable nodes such that all the check nodes that are neighbors of a node in \( S \) are connected to at least two nodes in \( S \). We dispense with this graphical representation of stopping sets in favor of an equivalent definition directly in terms of the underlying parity-check matrix \( H \). Thus we say that a stopping set is a set of columns of \( H \) with the property that the projection of \( H \) onto these columns does not contain a row of weight one\(^1\). The resulting definition of the stopping distance – the smallest size of a stopping set – bears a striking resemblance to the definition of the minimum Hamming distance of a linear code.

Recall that the minimum distance of a linear code \( C \) can be defined as the largest integer \( d(C) \) such that every \( d(C) - 1 \) or less columns of \( H \) are linearly independent. For binary codes, this is equivalent to saying that \( d(C) \) is the largest integer such that every set of \( d(C) - 1 \) or less columns of \( H \) contains at least one row of odd weight.

\(^1\)This explains why stopping sets stop the progress of an iterative decoder. A row of weight one — equivalently, a check node of degree one — would determine unambiguously an erased symbol. However, if an entire stopping set is erased, then all the neighboring check nodes are connected to these erasures at least twice, and thus form an under-constrained system of linear equations. In this case, an iterative decoder has no way of determining the erased values.

**Definition 1.** Let \( C \) be a linear code (not necessarily binary) and let \( H \) be a parity-check matrix for \( C \). Then the **stopping distance** of \( H \) is defined as the the largest integer \( s(H) \) such that every set of \( s(H) - 1 \) or less columns of \( H \) contains at least one row of weight one.

The following corollary is an immediate consequence of juxtaposing the definitions of \( s(H) \) and \( d(C) \) above.

**Corollary 1.** Let \( C \) be a linear code and let \( H \) be an arbitrary parity-check matrix for \( C \). Then \( s(H) \leq d(C) \).

Indeed, it is well known [7], [9], [14] that the support of every codeword is a stopping set, which is another way to see that \( s(H) \leq d(C) \) regardless of the choice of \( H \). Thus given a linear code \( C \), the largest stopping distance one could hope for is \( d(C) \), no matter how cleverly the Tanner graph for \( C \) is constructed. The point is that this bound can be *always* achieved by adding dependent rows to \( H \) (see Theorem 2). This makes the notion of the stopping distance, as a property of a code \( C \), somewhat meaningless: without restricting the number of rows in a parity-check matrix for \( C \), we cannot distinguish between the stopping distance and the conventional minimum distance. This observation, in turn, leads to the following definition.

**Definition 2.** Let \( C \) be a linear code with minimum Hamming distance \( d(C) \). Then the **stopping redundancy** of \( C \) is defined as the smallest integer \( \rho(C) \) such that there exists a parity-check matrix \( H \) for \( C \) with \( \rho(C) \) rows and \( s(H) = d(C) \).

The following theorem shows that the stopping redundancy is, indeed, well-defined.

**Theorem 2.** Let \( C \) be a linear code, and let \( H^* \) denote the parity-check matrix for \( C \) consisting of all the nonzero codewords of the dual code \( C^\perp \). Then \( s(H^*) = d(C) \).

**Proof:** Let \( [C^\perp] \) denote the \( |C^\perp| \times n \) matrix consisting of all the codewords of \( C^\perp \). It is well known (cf. [17, p.139]) that \( [C^\perp] \) is an orthogonal array of strength \( d(C) - 1 \). This means that any set of \( t \leq d(C) - 1 \) columns of \( [C^\perp] \) contains all the vectors of length \( t \) among its rows, each vector appearing the same number of times. In particular, any set of \( d(C) - 1 \) or less columns of \( [C^\perp] \) contains all the vectors of weight one among its rows. Clearly, the all-zero row can be removed from \( [C^\perp] \) to obtain \( H^* \), while preserving this property. \( \blacksquare \)

Theorem 2 also provides a trivial upper bound on the stopping redundancy. In particular, it follows from Theorem 2 that \( \rho(C) \leq 2^{d(C) - 1} \) for any binary linear code \( C \). This bound holds with equality in the degenerate case of the single-parity-check code. The next theorem determines \( \rho(C) \) exactly for all binary linear codes with minimum distance \( d(C) \leq 3 \).

**Theorem 3.** Let \( C \) be a binary linear code with minimum distance \( d(C) \leq 3 \). Then any parity-check matrix \( H \) for \( C \) satisfies \( s(H) = d(C) \), and therefore \( \rho(C) = r(C) \).

**Proof:** If \( H \) contains an all-zero column, then it is obvious that \( s(H) = d(C) = 1 \). Otherwise \( s(H) \geq 2 \), since then every single column of \( H \) must contain a row of weight one. Now, if \( d(C) = 3 \), then every two columns of \( H \) are distinct. This implies that these two columns must contain either the 01 row or the 10 row (or both). Hence \( s(H) = 3 \). \( \blacksquare \)
The following theorem, which is our main result in this section, shows that Theorem 3 is, in fact, a special case of a general upper bound on the stopping redundancy of linear codes.

**Theorem 4.** Let \( C \) be a binary linear code with minimum distance \( d(C) \geq 3 \). Then

\[
\rho(C) \leq (r(C) - 1) + (r(C) - 1) + \cdots + \left( \frac{r(C)}{d(C) - 1} \right) \tag{1}
\]

**Proof:** We first prove a slightly weaker result, which is conceptually simpler. Namely, let us show that

\[
\rho(C) \leq (r(C) - 1) + (r(C) - 1) + \cdots + \left( \frac{r(C)}{d(C) - 1} \right) \tag{2}
\]

Let \( H \) be an arbitrary parity-check matrix for \( C \) with \( r(C) \) linearly independent rows. Construct another parity-check matrix \( H' \) whose rows are all the linear combinations of \( t \) rows of \( H \), for all \( t = 1, 2, \ldots, d(C) - 1 \). Clearly, the number of rows of \( H' \) is given by the right-hand side of (1). Now let \( H_t \), respectively \( H_t' \), denote a matrix consisting of some \( t \) columns of \( H \), respectively the corresponding \( t \) columns of \( H' \). Observe that for all \( t \leq d(C) - 1 \), the \( t \) columns of \( H_t \) are linearly independent. This implies that the row-rank of \( H_t \) is \( t \), and therefore some \( t \) rows of \( H_t \) must form a basis for \( \mathbb{F}_2^t \). Hence the \( 2^t - 1 \) nonzero linear combinations of these \( t \) rows of \( H_t \) generate all the nonzero vectors in \( \mathbb{F}_2^t \), including all the vectors of weight one. But for \( t \leq d(C) - 1 \), the \( 2^t - 1 \) nonzero linear combinations of any \( t \) rows of \( H_t \) are among the rows of \( H_t' \) by construction. This proves that \( s(H') = d(C) \) and establishes (1).

To transition from (2) to (1), observe that we do not need to have all the nonzero vectors of \( \mathbb{F}_2^n \) among the rows of \( H_t' \); it would suffice to have at least one vector of weight one. Given a set \( S \subseteq \mathbb{F}_2^n \) and a positive integer \( m \), let \( mS \) denote the set of all vectors obtained as a linear combination of at most \( m \) vectors from \( S \). Define \( \mu(t) \) as the smallest integer with the property that for any basis \( B \) of \( \mathbb{F}_2^t \), the set \( \mu(t)B \) contains at least one vector of weight one. Then in the construction of \( H_t' \), it would suffice to take all the linear combinations of \( \mu(d(C) - 1) \) rows of \( H \). Clearly \( \mu(t) = t - 1 \) for all \( t \) (in fact, \( \mu(t) = t - 1 \) for all \( t \)), and the theorem follows.

The bound of (1), while much better than \( \rho(C) \leq 2^t - 1 \), is still too general to be tight for most codes. Nevertheless, we can conclude from Theorem 4 that when \( d(C) \) is a constant, the stopping redundancy is only polynomial in the (conventional) redundancy and, hence, in the length of the code.

In the next theorem, we provide a general lower bound on the stopping redundancy of linear codes.

**Theorem 5.** Let \( C \) be an arbitrary linear code of length \( n \). For each \( i = 1, 2, \ldots, d(C) - 1 \), define

\[
w_i \mathrel{\overset{\text{def}}{=}} \max \left\{ \left[ \frac{n + 1}{i} \right] - 1, d(C^\perp) \right\} \tag{3}
\]

Then

\[
\rho(C) \geq \frac{n}{i} \frac{n - w_i}{i - 1} \quad \text{for } i = 1, 2, \ldots, d(C) - 1
\]

**Proof:** Let \( H \) be a parity-check matrix for \( C \) and let \( \mathcal{I} \) be an arbitrary set of \( i \) column indices. We say that \( \mathcal{I} \) is an \( i \)-set. We also say that a row \( h \) of \( H \) covers \( \mathcal{I} \) if the projection of \( h \) onto \( \mathcal{I} \) has weight one. If \( s(H) = d(C) \), then each of the \( \binom{n}{i} \) \( i \)-sets must be covered by at least one row of the parity-check matrix, for all \( i = 1, 2, \ldots, d(C) - 1 \). Any single row of \( H \) of weight \( w \leq n - i + 1 \) covers exactly

\[
f_{n}(i, w) \overset{\text{def}}{=} \binom{n-w}{i-1} \tag{4}
\]

**Corollary 6.** Let \( C_1, C_2, \ldots, C_r \) be an infinite sequence of linear codes of strictly increasing length \( n_1, n_2, \ldots, n_r \) and fixed rate \( k_i/n_i = R \), with \( 0 < R < 1 \), such that \( d(C_i)/n_i \geq \delta_1 \) for all \( i \), with \( \delta_1 > 0 \). If also \( d(C_i^\perp)/n_i \geq \delta_2 \) for all \( i \), with \( \delta_2 > 0 \), then

\[
\rho(C_i) \geq \Omega \left( n - 12 \frac{\sqrt{H_2(\delta_1) - (1-\delta_2)H_2(\delta_1/2)}}{n} \right)
\]

**Proof:** We apply the bound of Theorem 5 with the size of an \( i \)-set given by \( d(C) - 1 \). It is easy to see that if \( d(C_i)/n_i \geq \delta_1 \) and \( d(C_i^\perp)/n_i \geq \delta_2 \) for all \( i \), then the maximum in (4) is attained at \( d(C_i^\perp) \) for all sufficiently large \( i \). Thus

\[
\rho(C_i) \geq \frac{n}{d(C_i^\perp)} \left( \frac{n - d(C_i^\perp)}{d(C_i^\perp)} - 2 \right) - 2
\]

where \( f(\delta_1, \delta_2) = H_2(\delta_1) - (1-\delta_2)H_2(\delta_1/2) \) and the second inequality follows from well-known bounds [17, p.309] on binomial coefficients in terms of \( H_2(\cdot) \).

We observe that the function \( f(\delta_1, \delta_2) \) defined in the proof of Corollary 6 is always positive, and therefore \( \rho(C_i) \) indeed grows exponentially with the length \( n \). Note that several well-known families of asymptotically good codes (for example, the self-dual codes [16]) satisfy the condition of Corollary 6.

**III. CONSTRUCTIONS OF CODES FROM OTHER CODES**

In this section, we examine several ways of constructing codes from other codes. While for most such constructions, it is trivial to determine the redundancy of the resulting code, we find it considerably more difficult to determine the resulting stopping redundancy, and resort to bounding it.
We start with two simple examples. The first example (Theorem 7) is the well-known direct-sum construction or, equivalently, the \((u, v)\) construction. The second one (Theorem 8) is the \((u, u)\) construction, or concatenation of a code with itself.

**Theorem 7.** Let \(C_1, C_2\) be \((n_1, k_1, d_1), (n_2, k_2, d_2)\) binary linear codes, respectively. Then \(C_3 = \{(u, v) : u \in C_1, v \in C_2\}\) is an \((n_1 + n_2, k_1 + k_2, \min(d_1, d_2))\) code with \(\rho(C_3) \leq \rho(C_1) + \rho(C_2)\).

**Proof:** Let \(H_1\) be an arbitrary \(\rho(C_1) \times n\) parity-check matrix for \(C_1\) with \(s(H_1) = d_1\), and let \(H_2\) be an arbitrary \(\rho(C_2) \times n\) parity-check matrix for \(C_2\) with \(s(H_2) = d_2\). Then

\[
H_3 = \begin{pmatrix} H_1 & 0 \\ 0 & H_2 \end{pmatrix}
\]

is a parity-check matrix for \(C_3\). Assume w.l.o.g. that \(d_1 \leq d_2\), so \(d(C_3) = d_1\). Label the columns of \(H_3\) by \(1, 2, \ldots, n_1 + n_2\), and let \(I\) be an arbitrary set of at most \(d(C_3) - 1\) column indices. If \(I \cap \{1, 2, \ldots, n_1\} \neq \emptyset\), the fact that \(s(H_1) = d(C_3)\) implies that there is a row of weight one in the projection of \(H_3\) onto \(I\). Otherwise \(I \subset \{n_1 + 1, n_1 + 2, \ldots, n_1 + n_2\}\), and the same conclusion follows from \(s(H_2) = d_2 \geq d(C_3)\). \(\blacksquare\)

**Theorem 8.** Let \(C_1\) be an \((n, k, d)\) binary linear code. Then the code \(C_2 = \{(u, u) : u \in C_1\}\) is a \((2n, k, 2d)\) code with \(\rho(C_2) \leq \rho(C_1) + n\).

**Proof:** Let \(H_1\) be a \(\rho(C_1) \times n\) parity-check matrix for \(C_1\) with \(s(H_1) = d\). Construct a parity-check matrix for \(C_2\) as

\[
H_2 = \begin{pmatrix} H_1 & 0 \\ 0 & I_n \end{pmatrix}
\]

where \(I_n\) is the \(n \times n\) identity matrix. Label the columns of \(H_2\) by \(0, 1, \ldots, 2n - 1\), and assume to the contrary there exists a set \(I \subset \{0, 1, \ldots, 2n - 1\}\) such that \(|I| \leq 2d - 1\) and there is no row of weight one in the projection of \(H_2\) onto \(I\). Let \(H_2(I)\) denote this projection. First note that the two identity matrices in \(H_2\) imply that if \(j \in I\), then also \((j + n) \mod 2n\) is in \(I\), since otherwise \(H_2(I)\) contains a row of weight one. It follows that \(I \cap \{0, 1, \ldots, n - 1\} \neq \emptyset\). But \(s(H_1) = d\), so the top part of \(H_2\) implies that \(|I \cap \{0, 1, \ldots, n - 1\}| \geq d\), otherwise \(H_2(I)\) again contains a row of weight one. By the first observation, we now conclude \(|I| \geq 2d\), a contradiction. \(\blacksquare\)

Here is an interesting observation about Theorems 7 and 8. It follows from 5 and 6 that if the constituent codes are optimal, in the sense that their stopping redundancy is equal to their redundancy, then the resulting code is also optimal. This indicates that the bounds in 5 and 6 are tight.

In contrast, the innocuous construction of extending a linear code \(C\) by adding an overall parity-check [17, p. 27] appears to be much more difficult to handle. The next theorem deals only with the special case where \(d(C) = 3\).

**Theorem 9.** Let \(C\) be an \((n, k, m)\) binary linear code. Then the extended code \(C'\) is an \((n + 1, k, 4)\) code with \(\rho(C') \leq 2\rho(C) + 2r(C') - 2\).

**Proof:** Let \(H\) be an arbitrary \(r(C) \times n\) parity-check matrix for \(C\). We construct a parity-check matrix for \(C'\) as follows

\[
H' = \begin{pmatrix} H & 0 \\ \overline{H} & 1 \end{pmatrix}
\]

where \(\overline{H}\) is the bitwise complement of \(H\), while 0 and 1 are the all-zero and the all-one column vectors, respectively. Label the columns in \(H'\) by \(1, 2, \ldots, n + 1\), and let \(I\) be a subset of \(\{1, 2, \ldots, n + 1\}\) with \(|I| \leq 3\). In fact, it would suffice to consider the case where \(I \subset \{1, 2, \ldots, n\}\) and \(|I| = 3\); all other cases easily follow from the fact that \(s(H) = 3\) by Theorem 3.

Let \(H(I)\) and \(\overline{H}(I)\) denote the projections of \(H\) and \(\overline{H}\), respectively, on the three positions in \(I\). If \(H(I)\) contains a row of weight one, we are done. If \(H(I)\) contains a row of weight two, we are also done — then the corresponding row in \(\overline{H}(I)\) has weight one. But otherwise, the only rows in \(H(I)\) are 000 and 111, which means that the three columns in \(H(I)\) are identical, a contradiction since \(d(C) = 3\). \(\blacksquare\)

The construction in Theorem 9 is not optimal. For example, if \(C'\) is the \((8, 4, 4)\) extended Hamming code, it produces a parity-check matrix for \(C'\) with 6 rows. However, \(C'\) is also the Reed-Muller code \(R(1, 3)\) for which we give in the next section a parity-check matrix \(H\) with \(s(H) = 4\) and only 5 rows.

**IV. REED-MULLER CODES**

We now focus on the well-known \((u, u + v)\) construction, in particular in connection with the recursive definition of binary Reed-Muller codes. Our goal is to derive a constructive upper bound on the stopping redundancy of \(R(r, m)\) — the binary Reed-Muller code of order \(r\) and length \(2^m\).

We begin by recalling several well-known facts. The reader is referred to [17, Chapter 13] for a proof of all these facts. For all \(r = 0, 1, \ldots, m\), the dimension of \(R(r, m)\) is \(k = \sum_{i=0}^{\left\lfloor \frac{m}{r} \right\rfloor} \binom{m}{i}\) and its minimum distance is \(d = 2^{m-r}\). Let \(G(r, m)\) be a generator matrix for \(R(r, m)\). Then, using the \((u, u + v)\) construction, \(G(r, m)\) can be defined recursively, as follows:

\[
G(r, m) = \begin{pmatrix} G(r, m - 1) & G(r, m - 1) \\ 0 & G(r - 1, m - 1) \end{pmatrix}
\]

with the recursion in (7) being bootstrapped by \(G(m, m) = I_{2^m}\) and \(G(0, m) = (11 \ldots 1)\) for all \(m\). By convention, the code \(R(-1, m)\) is the set \(\{0\}\) for all \(m\). Then

\[
R(r, m) = R(m - r - 1, m)
\]

for all \(m\) and all \(r = -1, 0, 1, \ldots, m\). It follows from 8 that \(G(r, m)\) is a parity-check matrix for \(R(m - r - 1, m)\), a code with minimum distance \(2^{r+1}\). Hence every \(2^{r+1} - 1\) columns of \(G(r, m)\) are linearly independent.

Our objective in what follows is to construct an alternative parity-check matrix \(H(r, m)\) for \(R(m - r - 1, m)\) such that \(s(H(r, m)) = 2^{r+1}\). Then the number of rows in \(H(r, m)\) gives an upper bound on the stopping redundancy of \(R(m - r - 1, m)\) (and the number of rows in \(H(m - r - 1, m)\) is an upper bound on the stopping redundancy of \(R(r, m)\)). Here is the recursive construction that we will use.
Recursive Construction A: For all positive integers \( m \) and for all \( r = 1, 2, \ldots, m - 2 \), we define:

\[
H(r, m) = \begin{pmatrix} H_{\text{top}} & \left( \begin{array}{c} H(r, m - 1) \\ H(r - 1, m - 1) \end{array} \right) \\ \begin{array}{c} 0 \\ H(r - 1, m - 1) \end{array} \end{pmatrix}
\]

with the recursion in (9) being bootstrapped as follows: for all \( m = 0, 1, \ldots \), the matrices \( H(0, m) \), \( H(m-1, m) \), \( H(m, m) \) are defined by

\[
H(0, m) = \begin{pmatrix} G(0, m) = (11 \cdots 1) \\ \begin{array}{c} G(m-1, m) \\ G(m, m) = I_{2^m} \end{array} \end{pmatrix}
\]

Proposition 10. \( H(m, m) \) is a generator matrix for \( R(r, m) \) and, hence, a parity-check matrix for \( R(m-r, m) \).

\[
\begin{aligned}
R(r, m) &= \{ (u, u+v) : u \in C_1, v \in C_2 \} \\
C_1 &= R(r, m-1) \\
C_2 &= R(r-1, m-1)
\end{aligned}
\]

where each row of \( H_{\text{bot}} \) can be written as

\[(v, 0) = (v, v) + (0, v)\]

The stopping distance of \( R(r, m) \) is \( 2^{r+1} \) for all positive integers \( m \) and for all \( r = 0, 1, \ldots, m-1 \).

Proposition 12. The stopping distance of \( H(r, m) \) is \( 2^{r+1} \) for all positive integers \( m \) and for all \( r = 0, 1, \ldots, m-1 \).

\[
\begin{aligned}
\text{Proof:} &\text{ The proof is by induction on } m \text{ and } r. \text{ Lemmata} \text{ in conjunction with the fact that the stopping distance of } H(0, m) \text{ is } 2 \text{ establish the induction base. For the induction step, let } I \subseteq \{0, 1, \ldots, 2^{m-1} - 1\} \text{ be a set of column indices such that } |I| \leq 2^{2m-1} - 1. \text{ We distinguish between three easy cases.} \\
\text{Case 1: } &I \cap \{0, 1, \ldots, 2^{m-1} - 1\} = \emptyset. \text{ Then } I \subseteq \{2^{m-1}, 2^{m-1}+1, \ldots, 2^m - 1\}. \text{ By induction hypothesis, the stopping distance of } H(r, m-1) \text{ is } 2^{r+1}. \text{ Hence the top row in (9) implies that the projection of } H(r, m) \text{ onto } I \text{ contains a row of weight one.} \\
\text{Case 2: } &1 \leq |I \cap \{0, 1, \ldots, 2^{m-1} - 1\}| \leq 2^r. \text{ By induction hypothesis, } H(r-1, m-1) \text{ has a stopping distance of } 2^r. \text{ Hence the bottom row in (9) implies that the projection of } H(r, m) \text{ onto } I \text{ contains a row of weight one.} \\
\text{Case 3: } &|I \cap \{0, 1, \ldots, 2^{m-1} - 1\}| \geq 2^r. \text{ By induction hypothesis, } H(r-1, m-1) \text{ has a stopping distance of } 2^r. \text{ Hence the bottom row in (9) implies that the projection of } H(r, m) \text{ onto } I \text{ contains a row of weight one.} \\
\end{aligned}
\]

Theorem 14. For all \( m = 1, 2, \ldots \) and for all \( r = 0, 1, \ldots, m \), the stopping redundancy of \( R(r, m) \) is upper bounded by

\[
\rho(R(r, m)) \leq \sum_{i=0}^{m-1} \binom{r+i}{i} 2^i
\]
Proof: Follows immediately from \(8\), Proposition\(10\) Proposition\(12\) and Lemma\(13\).\]

To see how far the bound of Theorem\(14\) is from the (conventional) redundancy of Reed-Muller codes, we first need the following technical lemma.

Lemma 15. For all positive integers \(m\) and all \(0 \leq r \leq m-1\), we have

\[
\sum_{i=0}^{r} \binom{m-r-1+i}{i} 2^{i} - \sum_{i=0}^{r} \binom{m}{i} = 2^{r}(m) \tag{17}
\]

Proof: Denote the sum \(\sum_{i=0}^{r} \binom{m}{i}\) by \(S(m,r)\). Using the well-known \(\binom{m}{n} = \binom{m-1}{n} + \binom{m-1}{n-1}\) recursion, we obtain

\[
S(m,r) = \binom{m-1}{r} + 2 \sum_{i=0}^{r-1} \binom{m-1}{i}
\]

and recognize the second term above as \(2S(m-1,r-1)\). The result now follows by induction on \(m\) and \(r\). \(\blacksquare\)

Using Lemma\(15\) we can establish a relation between the redundancy of Reed-Muller codes and their stopping redundancy. For this, it will be more convenient to work with the dual code \(\mathcal{C} = R(r,m)^{\perp}\). Recall that \(r(\mathcal{C}) = \sum_{i=0}^{m} \binom{m}{i}\). Comparing this to the bound on \(\rho(\mathcal{C})\) in Theorem\(12\) we find that

\[
\rho(\mathcal{C}) \leq \sum_{i=0}^{r} \binom{m-r-1+i}{i} 2^{i} \leq 2 \sum_{i=0}^{r} \binom{m}{i} = 2^{r}(m)\tag{17}
\]

where the second inequality follows from \(17\). Therefore, for any fixed order \(r\), the stopping redundancy of \(R(r,m)^{\perp}\) is at most the redundancy of \(R(r,m)^{\perp}\) times a constant. Alternatively, if we take \(\mathcal{C} = R(r,m)\), then Theorem\(14\) implies that \(\rho(\mathcal{C}) \leq d(\mathcal{C})r(\mathcal{C})/2\). Thus for any fixed \(d(\mathcal{C})\), the increase in redundancy is by a constant factor.

V. GOLAY CODES

The \((24,12,8)\) binary Golay code \(G_{24}\) is arguably the most remarkable binary block code. It is often used as a benchmark in studies of code structure and decoding algorithms.

There are several “canonical” parity-check matrices for \(G_{24}\), see \cite{3,4,23}\) and other papers. Our starting point is the systematic double-circuit matrix \(H_{24}\) given in MacWilliams and Sloane \cite[p.65]{24}\) and shown in Table\(I\). It can be readily verified that \(s(H_{24}) = 4\), which means that \(H_{24}\) achieves only half of the maximum possible stopping distance. Curiously, the stopping distance of the two “trellis-oriented” parity-check matrices for \(G_{24}\), given in \cite[p.2060]{23}\) and \cite[p.1441]{3}\), is also 4.

Computing the general bounds of Theorems\(14\) and \(15\) for the special case of \(G_{24}\) produces the extremely weak result:

\[
6 \leq \rho(G_{24}) \leq 2509
\]

Having tried several methods to construct a parity-check matrix for \(G_{24}\) with stopping distance 8, our best result was achieved using a greedy (lexicographic) computer search. Specifically, with the 4095 nonzero vectors of \(G_{24}\) listed lexicographically, we iteratively construct the parity-check matrix \(H'_{24}\), at each iteration adjoining to \(H_{24}\) the first vector on the list with the highest score. Each vector receives \(i\) points to its score for each yet uncovered \(i\)-set it covers, where \(i \in \{1,2,\ldots,7\}\) (cf. Theorem\(5\)). The resulting matrix is given in Table\(II\). Since \(H'_{24}\) has only 34 rows and \(s(H'_{24}) = 8\), it follows that the stopping redundancy of \(G_{24}\) is at most 34.

| Total Patterns | \(\Psi_{ML}(w)\) | \(\Psi_{H_{24}}(w)\) | \(\Psi_{H'_{24}}(w)\) |
|----------------|------------------|----------------------|----------------------|
| 0              | 1                | 0                    | 0                    |
| 1              | 24               | 0                    | 0                    |
| 2              | 276              | 0                    | 0                    |
| 3              | 2024             | 0                    | 0                    |
| 4              | 10626            | 0                    | 0                    |
| 5              | 45204            | 0                    | 0                    |
| 6              | 134596           | 0                    | 0                    |
| 7              | 436104           | 0                    | 0                    |
| 8              | 735471           | 0                    | 0                    |
| 9              | 1307504          | 0                    | 0                    |
| 10             | 1961256          | 0                    | 0                    |
| 11             | 2496144          | 0                    | 0                    |
| 12             | 2701156          | 0                    | 0                    |
| 13             | \(24\)           | \(24\)               | \(24\)               |

To appear in the IEEE Transactions on Information Theory, vol. 52, No. 3, March 2006
To evaluate the effect of increasing the stopping distance, it would be interesting to compare the performance of iterative decoders for $G_{24}$ based on $H_{24}$ or $H'_{24}$, respectively. As a baseline for such a comparison, it would be also useful to have the performance of a maximum-likelihood decoder for $G_{24}$. In what follows, we give analytic expressions for the performance of the three decoders on the binary erasure channel (BEC).

Clearly, a maximum-likelihood decoder fails to decode (recover) a given erasure pattern if and only if this pattern contains the support of (at least one) nonzero codeword of $G_{24}$. Let $\Psi_{\text{ML}}(w)$ denote the number of such erasure patterns as a function of their weight $w$. Then

$$
\Pr_{\text{ML}}(\text{decoding failure}) = \sum_{w=0}^{24} \Psi_{\text{ML}}(w) p^w (1-p)^{24-w}
$$

where $p$ is the erasure probability of the BEC. In contrast, an iterative decoder (based on $H_{24}$ or $H'_{24}$) fails if and only if the erasure pattern contains a stopping set. Thus

$$
\Pr_{H_{24}}(\text{decoding failure}) = \sum_{w=0}^{24} \Psi_{H_{24}}(w) p^w (1-p)^{24-w}
$$

$$
\Pr_{H'_{24}}(\text{decoding failure}) = \sum_{w=0}^{24} \Psi_{H'_{24}}(w) p^w (1-p)^{24-w}
$$

where $\Psi_{H_{24}}(w)$ and $\Psi_{H'_{24}}(w)$ denote the number of erasure patterns of weight $w$ that contain a stopping set of $H_{24}$ and $H'_{24}$, respectively. It remains to compute $\Psi_{H_{24}}$, $\Psi_{H'_{24}}$, and $\Psi_{\text{ML}}$.

Obviously, $\Psi_{\text{ML}}(w) = 0$ for $w \leq 7$ and $\Psi_{\text{ML}}(w) = (24)$ for $w \geq 13$ (any 13 columns of a parity-check matrix for $G_{24}$ are linearly dependent). For the other values of $w$, we have

$$
\Psi_{\text{ML}}(w) = \begin{cases} 
(16)_{w-8} & 8 \leq w \leq 11 \\
759 & w = 12 \\
1771(20 + 720) + 2576 & w = 13
\end{cases}
$$

where we made use of Table IV of [5] (for $w = 12$, we have $\Psi_{\text{ML}}(w) = |X_{12}| + |S_{12}| + |U_{12}|$ in the notation of [5]). To find $\Psi_{H_{24}}(\cdot)$ and $\Psi_{H'_{24}}(\cdot)$, we used exhaustive computer search.

These functions are given in Table III. The resulting probabilities of decoding failure are plotted in Figure 1. Note that while we may add rows to $H'_{24}$ to eliminate more stopping sets, this would have negligible effect since the slope of the performance curve is dominated by the smallest $w$ for which $\Psi_{H'_{24}}(w) \neq 0$.

![Figure 1](image-url)

**Figure 1.** The decoding failure probability of three decoders for $G_{24}$: a maximum-likelihood decoder and iterative decoders based upon $H_{24}$ and $H'_{24}$.

### Table III

| $w$ | Total Patterns | $\Psi_{\text{ML}}(w)$ | $\Psi_{H_{12}}(w)$ | $\Psi_{H'_{12}}(w)$ |
|-----|----------------|----------------------|--------------------|---------------------|
| 0   | 1              | 0                    | 0                  | 0                   |
| 1   | 12             | 0                    | 0                  | 0                   |
| 2   | 66             | 0                    | 0                  | 0                   |
| 3   | 220            | 0                    | 0                  | 0                   |
| 4   | 495            | 0                    | 0                  | 0                   |
| 5   | 792            | 0                    | 0                  | 0                   |
| 6   | 924            | 0                    | 0                  | 0                   |
| $\geq 7$ | $(12)_w$ | $(12)_w$ | $(12)_w$ | $(12)_w$ |

The $(12, 6, 6)$ extended ternary Golay code $G_{12}$ is another famous code. A systematic double-circulant parity-check matrix for $G_{12}$ is given in [17, p. 510]; this matrix is denoted $H_{12}$ in Table III. It is easy to see that $s(H_{12}) = 3$, which is again half of the maximum possible stopping distance. Using greedy lexicographic search, we have constructed a parity-check matrix $H'_{12}$ with stopping distance 6 and only 22 rows. This matrix is also given in Table III. The number of undecodable erasure patterns for a maximum-likelihood decoder and for the iterative decoder based on $H_{12}$ and $H'_{12}$ is given in Table IV.

### Table IV

| $w$ | Total Patterns | $\Psi_{\text{ML}}(w)$ | $\Psi_{H_{12}}(w)$ | $\Psi_{H'_{12}}(w)$ |
|-----|----------------|----------------------|--------------------|---------------------|
| 0   | 1              | 0                    | 0                  | 0                   |
| 1   | 12             | 0                    | 0                  | 0                   |
| 2   | 66             | 0                    | 0                  | 0                   |
| 3   | 220            | 0                    | 0                  | 0                   |
| 4   | 495            | 0                    | 0                  | 0                   |
| 5   | 792            | 0                    | 0                  | 0                   |
| 6   | 924            | 0                    | 0                  | 0                   |
| $\geq 7$ | $(12)_w$ | $(12)_w$ | $(12)_w$ | $(12)_w$ |

### VI. MDS Codes

The last family of codes we investigate are the maximum distance separable (MDS) codes. These codes have intricate algebraic and combinatorial structure [17, Chapter 11]. In particu-
lar, if \( C \) is an \((n, k, d)\) linear\(^2\) MDS code, then the dual code \( C^\perp \) is also MDS and its distance is \( d^\perp = k + 1 = n - d + 2 \). Moreover, every \( d \) positions in \( \{1, 2, \ldots, n\} \) are the support of a codeword of \( C \) of weight \( d \), while every \( d^\perp \) positions support a codeword of \( C^\perp \) of weight \( d^\perp \). We will use these and other properties of MDS codes to establish sharp upper and lower bounds on their stopping redundancy.

**Theorem 16.** Let \( C \) be an \((n, k, d)\) MDS code with \( d \geq 2 \). Then

\[
\frac{1}{d-1} \binom{n}{d-2} \leq \rho(C) \leq \binom{n}{d-2} \tag{18}
\]

**Proof:** The lower bound is just a special case of Theorem\(^5\) Taking \( i = d - 1 \) in \( (3) \), we find that

\[ w_{d-1} = d(C^\perp) = n - d + 2 \]

whenever \( d \geq 2 \), so that \( n - w_{d-1} = d - 2 \). The corresponding lower bound in Theorem\(^5\) thus reduces to

\[
\rho(C) \geq \frac{\binom{n}{d-1}}{(n-d+2)d-2} = \frac{1}{d-1}\binom{n}{d-2} \tag{19}
\]

To prove the upper bound, note that every \( d^\perp = n - d + 2 \) positions support a codeword of \( C^\perp \). We take one such codeword of \( C^\perp \) for every set of \( d^\perp \) positions, and use the resulting

\[
\binom{n}{d^\perp} = \binom{n}{n-d+2} = \binom{n}{d-2}
\]

codewords as rows of a matrix \( H \). We claim that \( H \) is a parity-check matrix for \( C \), namely that \( \text{rank}(H) = n - k = d - 1 \). Indeed, consider a set of \( d - 1 \) positions, say \( \{1, 2, \ldots, d-1\} \). For each \( i \in \{1, 2, \ldots, d-1\} \), there is a row of \( H \) of weight \( d^\perp = n - (d-1) + 1 \) such that the intersection of its support with \( \{1, 2, \ldots, d-1\} \) is \( \{i\} \). The corresponding \( d - 1 \) rows of \( H \) thus contain an identity matrix on the first \( d - 1 \) positions; hence \( \text{rank}(H) = d - 1 \). It remains to show that \( s(H) = d \). But this follows immediately from what we have already proved: given any set \( \mathcal{I} \subset \{1, 2, \ldots, n\} \) with \( |\mathcal{I}| = d - 1 \), there is a corresponding set of \( d - 1 \) rows of \( H \) whose projection on the positions in \( \mathcal{I} \) is the identity matrix.

Both bounds in Theorem\(^{16}\) are exact if \( d = 2 \). Indeed, for \( d = 2 \) the upper and lower bounds in \( (18) \) coincide, yielding \( \rho(C) = 1 \). This reflects the degenerate case of the \((n, n-1, 2)\) MDS code \( C \), whose dual is the \((n, 1, n)\) repetition code \( C' \). Indeed, any codeword of \( C' \) can serve as a \( 1 \times n \) parity-check matrix \( H \) for \( C \) with \( s(H) = 2 \). In the case of the \((n, 1, n)\) repetition code \( C' \) itself, the bounds in \( (18) \) reduce to

\[
\frac{n}{2} \leq \rho(C') \leq \frac{n(n-1)}{2}
\]

The true value is \( \rho(C') = r(C') = n - 1 \). To see this, consider an \((n-1) \times n \) parity-check matrix \( H' \) for \( C' \) such that the support of the \( i \)-th row in \( H' \) is \( \{i, i+1\} \) for \( i = 1, 2, \ldots, n - 1 \).

Next, we use a combinatorial argument to show that \( d = 2 \) is the only case where the lower bound of Theorem\(^{15}\) is exact.

**Theorem 17.** Let \( C \) be an \((n, k, d)\) MDS code with \( d \geq 3 \). Then

\[
\rho(C) \geq \frac{1}{d-1} \left( \frac{n}{d-2} \right) + 1 \tag{20}
\]

**Proof:** Assume to the contrary that there is a parity-check matrix \( H \) for \( C \) with \( s(H) = d \) and at most \( (d-2)/(d-1) \) rows. As in Theorem\(^{5}\) we say that a given set \( \mathcal{I} \subset \{1, 2, \ldots, n\} \) with \( |\mathcal{I}| = i \) is an \( i \)-set, and that a row \( h \) of \( H \) covers an \( i \)-set \( \mathcal{I} \) if the projection of \( h \) on \( \mathcal{I} \) has weight one. The number of \((d-1)\)-sets covered by a single row of weight \( w \geq d^\perp \)

\[
D_{n,d}(w) = \begin{cases} w \frac{n-w}{d-2} & w = d = n - d + 2 \\ 0 & w > d = n - d + 2 \end{cases} \tag{21}
\]

The total number of \((d-1)\)-sets is \( \binom{n}{d-1} \) and every one of them must be covered by at least one row of \( H \). But

\[
\max_{w \geq d^\perp} D_{n,d}(w) = \frac{\binom{n}{d-1}}{d^\perp} = \frac{1}{d-1} \frac{n}{d-2} \tag{22}
\]

in view of \( (21) \). It now follows from \( (22) \) that there are exactly \( \frac{\binom{n}{d-1}}{d^\perp} \) rows of \( H \), all of weight \( w = d^\perp \), and that each \((d-1)\)-set is covered by exactly one row of \( H \). The latter condition is equivalent to saying that each (complementary) set of \( n - (d-1) = d^\perp - 1 \) positions is contained in the support of exactly one row of \( H \). In other words, the supports of the rows of \( H \) form an \( S(d^\perp-1, d^\perp, n) \) Steiner system.\(^3\)

Such a Steiner system may or may not exist. If it does not exist we are done, but in many known cases (e.g. \( S(2,3,7), S(3,4,8), S(4,5,11), \ldots \)) it does; hence we must proceed to establish another contradiction. To this end, consider a \((d-2)\)-set which is the complement of the support of a given row \( h_1 \) of \( H \). As \( s(H) = d \), this \((d-2)\)-set must be covered by some other row of \( H \), say \( h_2 \).

But then

\[
|\text{supp}(h_1) \cap \text{supp}(h_2)| = d^\perp - 1
\]

The above means that there is a set of \( d^\perp - 1 \) positions that is contained in two different blocks of the \( S(d^\perp-1, d^\perp, n) \) Steiner system, a contradiction.\(^\boxdot\)

**Example.** The hexcode \( H_{6} \) is a remarkable \((6,3,4)\) MDS code over \( \mathbb{F}_4 = \{0, 1, \omega, \omega^2\} \). It is unique up to monomial equivalence and self-dual under the Hermitian inner product (so the conjugate of a parity-check matrix for \( H_{6} \) is a generator matrix for \( H_{6} \)). The upper and lower bounds in \( (18) \) imply that \( 5 \leq \rho(H_{6}) \leq 15 \). Using one of the covering designs (see below) in \( (10) \), we construct the following parity-check matrix

\[
\begin{bmatrix}
\end{bmatrix}
\]

\(^2\)Throughout this section, we deal with linear MDS codes only. Henceforth, whenever we say “an MDS code” we mean a linear MDS code.

\(^3\)An \( S(t, k, v) \) Steiner system is a set of \( k \)-subsets of \( \{1,2,\ldots,v\} \), called blocks, so that each \( t \)-subset of \( \{1,2,\ldots,v\} \) is contained in exactly one block.
for $\mathcal{H}_0$. It can be easily verified by hand that $s(H) = 4$, and therefore $\rho(\mathcal{H}_0) \leq 6$. Finally, the lower bound of Theorem 17 proves that $\rho(\mathcal{H}_0) = 6$. Thus (20) is exact in this case. □

In general, it follows from the proof of Theorem 17 that if $C$ is an $(n,k,d)$ MDS code and $H$ is a parity-check matrix for $C$ with $s(H) = d$, then the supports of rows of weight $d^\perp$ in $H$ form a $(n,d^\perp,d^\perp-1)$ covering design. A $(v,k,t)$ covering design is a collection of subsets of size $k$ of $\{1,2,\ldots,v\}$, called blocks, such that every subset of $\{1,2,\ldots,v\}$ of size $t$ is contained in at least one block (changing “at least one” to “exactly one” thus makes this a Steiner system). The smallest number of blocks in a $(v,k,t)$ covering design is usually denoted by $C(v,k,t)$ and called the covering number (see [11],[18] and references therein). Thus if $C$ is an $(n,k,d)$ MDS code, then

$$\rho(C) \geq C(n,d^\perp,d^\perp-1) = C(n,k+1,k) \quad (24)$$

The best general lower bound on the covering number dates back to the work of Schönheim [21], who showed in 1964 that $C(v,k,t) \geq (v/k) C(v-1,k-1,t-1)$. For the special case of (24), this proves that

$$\rho(C) \geq \left\lceil \frac{n-1}{k+1} \left\lfloor \frac{n-2}{k-1} \left\lfloor \frac{n-k+1}{2} \right\rfloor \cdots \right\rfloor \right\rceil \quad (25)$$

Notice that if we ignore all the ceilings in (25), then we recover precisely the lower bound in (18). Hence (25) is always at least as strong as the lower bound of Theorem 16. An alternative bound on the covering number is due to de Caen [6] (see also [10, p. 270]). In our case, this bound reduces to

$$\rho(C) \geq \frac{k+1}{(k+2)(d-2)} \left( \frac{n}{d-2} \right) \quad (26)$$

This is better than the lower bound of Theorem 16 if and only if $n > 2(k+1) = 2d^\perp$. Note that Theorem 17 is sometimes stronger than both (25) and (26), for example in those cases where $n \leq 2d^\perp$ and an $S(k+1,n)$ Steiner system exists.

We can now summarize most of the results in this section as follows. If $C$ is an $(n,k,d)$ MDS code over $\mathbb{F}_q$ with $d \geq 3$, the stopping redundancy of $C$ is in the range

$$\frac{1}{d-1} \left( \frac{n}{d-2} \right) < \rho(C) \leq \frac{\max\{d^\perp,d^\perp-1\}}{n} \left( \frac{n}{d-2} \right) \quad (27)$$

(see Appendix for a proof of the upper bound). These bounds are reasonably close and, notably, do not depend on the size of the field. Determining the stopping redundancy of MDS codes exactly appears to be a difficult combinatorial problem. In view of (25), it is likely to be at least as difficult as the problem of determining the covering number $C(n,k+1,k)$.

**VII. Discussion and Open Problems**

This paper only scratches the surface of the many interesting and important problems that arise in the investigation of stopping redundancy. The importance of stopping sets is well understood in the case of the binary erasure channel. However, the concept of stopping redundancy is new. Figure 1 clearly demonstrates that it is the stopping sets of size strictly less than the minimum distance that are responsible for the performance gap between maximum-likelihood and iterative decoding. Thus eliminating such stopping sets is what we need to do, and the stopping redundancy is the relevant figure of merit.

It would be extremely interesting to understand how relevant stopping redundancy is for other channels. In this regard, it is worth mentioning the following observation of Feldman [9, p. 176]. In the general framework of LP decoding, the support of any pseudocodeword is a stopping set for any channel. Thus the stopping redundancy might be the relevant figure of merit in this, very general, context as well.

It is interesting to note that although we have defined and studied the stopping redundancy as a property of linear codes, it turns out to be closely related to a number of well-known combinatorial structures. Steiner systems and covering designs were already discussed in Section VI. A combinatorial structure equivalent to a covering design is the Turán system. For more information on this, we refer the reader to [13],[18],[22]. Another combinatorial concept that is very closely related to stopping redundancy is that of $k$-locally-thin families. A family $\mathcal{F}$ of subsets of the set $\{1,2,\ldots,\rho\}$ is said to be $k$-locally-thin if given any $k$ distinct subsets in $\mathcal{F}$, there is at least one element $i \in \{1,2,\ldots,\rho\}$ that is contained in exactly one of them. The central problem in the study of $k$-locally-thin families is to determine $M(\rho,k)$, defined as the maximum cardinality of a $k$-locally-thin family of subsets of $\{1,2,\ldots,\rho\}$. In particular, one would like to determine the sequence

$$t(k) \overset{\text{def}}{=} \limsup_{\rho \to \infty} \frac{\log_2 M(\rho,k)}{\rho} \quad (27)$$

But $M(\rho,k)$ is also the maximum number of columns in a binary matrix $H$ with $\rho$ rows, distinct columns, and no stopping set of size $k$. Hence, results on stopping redundancy might be relevant in the study of $k$-locally-thin families, and vice versa. For example, our construction in Section IV produces a parity-check matrix for the Reed-Muller code $R(m-2,m)$ of length $n = 2^m$ distance 4, and stopping redundancy $(2 + o(1)) \log_2 n$, thereby showing that $t(3) \geq 1/2$. It should be pointed out that estimating $t(k)$ is a notoriously difficult task. In fact, it is not even known whether $t(3) < 1$ and whether $t(k)$ decreases monotonically with $k$. For much more on this, see [1],[2],[15], and references therein.

We have concluded the original version of this paper with a variety of research questions related to our results. Although some of these questions have been since answered (see below), we repeat them here. In Section IV we derived upper and lower bounds on the stopping redundancy of general binary linear codes. Can these general bounds be improved? In particular, is there an asymptotically good family of codes such that their stopping redundancy grows only polynomially fast with their
length? In Section IV we have examined only a small sample of the multitude of known ways of combining codes to construct other codes. What can be said of the stopping redundancy of other constructions, in particular constructions involving nonbinary alphabets, such as concatenated/multilevel coding? In Sections V and VI we investigated the Reed-Muller codes and the Golay codes. Are the constructions provided therein optimal? In particular, is it true that \( \rho(G_{24}) = 34 \)? It appears that proving lower bounds on the stopping redundancy, even for specific codes such as \( G_{24} \), is quite difficult. Finally, in Section VII we considered MDS codes. We conjecture that the stopping redundancy of an \((n, k, d)\) MDS code over \( \mathbb{F}_q \) does not depend on the code, but only on its parameters \( n \) and \( k \). In other words, any two \((n, k, d)\) MDS codes have the same stopping redundancy. If this conjecture is true, then it should be possible, in principle, to determine the stopping redundancy of an \((n, k, d)\) MDS code as a function of \( n \) and \( k \). However, this appears to be a difficult combinatorial problem.

Finally, we would like to mention two recent papers that are directly inspired by our results, and improve upon them. Etzion [8] studies in detail the stopping redundancy of binary Reed-Muller codes. He proves that the stopping redundancy of \( \mathcal{R}(m - 2, 2) \), which is also the extended Hamming code of length \( 2^m \), is \( 2m - 1 \). This shows that our construction in Section IV is optimal in this case. However, it turns out that this construction is not optimal for the first-order Reed-Muller codes \( \mathcal{R}(1, m) \); Etzion [8] derives a better upper bound on the stopping redundancy of these codes. Han and Siegel [13] use the “probabilistic method” to establish upper bounds on the stopping redundancy of general linear codes, which improve significantly upon our result in Theorem 4. They also prove upper bounds on the stopping redundancy of MDS codes in terms of Turán numbers, that are stronger than our Corollary 20.

**APPENDIX**

**AN IMPROVED UPPER BOUND ON THE STopping REDUNDANCY OF MDS BOUNDS**

In this appendix, we improve the upper bound in Theorem 16 using constant-weight codes. An \((n, 4, w)\) constant-weight code \( \mathcal{C} \) is a set of binary vectors of length \( n \) and weight \( w \), such that any two elements of \( \mathcal{C} \) are at distance \( \geq 4 \) from each other. Let \( U(n, w, m) \) denote the largest possible cardinality of a union of \( m \) constant-weight codes, each with parameters \((n, 4, w)\).

**Theorem 18.** Let \( \mathcal{C} \) be an \((n, k, d)\) MDS code with \( d \geq 3 \). Set \( m = \min\{k, n - k - 1\} \). Then

\[
\rho(\mathcal{C}) \leq \left( \frac{n}{d - 2} \right) - U(n, d - 2, m) \tag{28}
\]

**Proof:** We start as in the proof of Theorem 16 by constructing a parity-check matrix \( H \) for \( \mathcal{C} \) such that the supports\(^4\) of the rows of \( H \) are all the binary vectors of length \( n \) and weight \( d = n - d + 2 \). Now let \( C_1, C_2, \ldots, C_m \) be any \( m \) constant-weight codes with parameters \((n, 4, n - d + 2)\). We remove from \( H \) all the rows whose supports belong to \( C_1 \cup C_2 \cup \cdots \cup C_m \). Let \( H' \) denote the resulting matrix. Since obviously

\[
U(n, n - d + 2, m) = U(n, d - 2, m)
\]

the number of rows remaining in \( H' \) is given by the right-hand side of (29), provided \( C_1, C_2, \ldots, C_m \) are chosen so as to maximize the cardinality of their union. We claim that \( s(H') = d \).

To prove this claim, we distinguish between two cases.

**Case 1:** Consider a \((d - 1)\)-set. As shown in the proof of Theorem 16 there are some \( d - 1 \) rows in \( H \) such that the projection of their supports on the \((d - 1)\)-set is the \((d - 1) \times (d - 1)\) identity matrix. Let \( \mathcal{D} \subset \mathbb{F}_2^d \) denote this set of \( d - 1 \) supports. Any two elements of \( \mathcal{D} \) are at distance exactly 2 from each other, since \((d - 1) + (d - 1) = d \). Hence \( |\mathcal{D}| \leq 1 \) for all \( i \). As \( m \leq n - k - 1 = d - 2 = |\mathcal{D}| - 1 \), it follows that \( H' \) contains at least one row whose support belongs to \( \mathcal{D} \).

**Case 2:** Consider a \( t \)-set with \( t \leq d - 2 \) and assume w.l.o.g. that this \( t \)-set is \( \{1, 2, \ldots, t\} \). Note that \( H \) contains some \( d - 1 \) rows whose supports are

\[
\{t, t + 1, \ldots, t + d - 1\} \setminus \{t + i\} \quad \text{for} \quad i = 1, 2, \ldots, d - 1
\]

As before, let \( \mathcal{D} \) denote this set of \( d - 1 \) supports. The intersection of each support in \( \mathcal{D} \) with the \( t \)-set \( \{1, 2, \ldots, t\} \) is \( \{t\} \), so the projection of each of the corresponding \( d - 1 \) rows of \( H \) onto this \( t \)-set has weight one. Moreover, any two elements of \( \mathcal{D} \) are, again, at Hamming distance 2 from each other. Hence \( |\mathcal{D}| \leq 1 \) for all \( i \), and since \( m \leq k = d - 1 \), it follows that \( H' \) contains at least one row whose support is in \( \mathcal{D} \).

It remains to show that \( \text{rank}(H') = n - k = d - 1 \). But this follows from the fact that \( s(H') = d \). Indeed, up to an appropriate column permutation, there is a row in \( H' \) such that the intersection of its support with \( \{1, 2, \ldots, d - 1\} \) is \( \{d - 1\} \). Then, there is another row in \( H' \) such that the intersection of its support with \( \{1, 2, \ldots, d - 2\} \) is \( \{d - 2\} \), again up to a column permutation. Continuing in this manner, we get a set of \( d - 1 \) rows of \( H' \) whose projection on the first \( d - 1 \) positions is an upper-triangular matrix with nonzero entries on the main diagonal. Hence \( \text{rank}(H') = d - 1 \), and we are done.

**Proposition 19.** For all positive integers \( n \) and \( w \) with \( w \leq n \) and for all \( m \leq n \),

\[
U(n, w, m) \geq \frac{m}{n} \binom{n}{w} \tag{29}
\]

**Proof:** Graham and Sloane [12, Theorem 1] construct a partition of the set of binary vectors of length \( n \) and weight \( w \) into \( n \) constant-weight codes with parameters \((n, 4, w)\). Taking the \( m \) largest codes in such a partition proves (29).

**Corollary 20.** Let \( \mathcal{C} \) be an \((n, k, d)\) MDS code. Then

\[
\rho(\mathcal{C}) \leq \frac{\max\{d, d - 1\}}{n} \binom{n}{d - 2} \tag{30}
\]

**Proof:** Follows immediately from Theorem 18 and Proposition 19. Note that (30) coincides with (18) iff \( d = 2 \).

**Acknowledgment**

We are grateful to Ilya Dumer, Tuvi Etzion, Jonathan Feldman, and Paul Siegel for helpful and stimulating discussions.
