SUMMARY
We provide a complete description of possible distributions consistent with any Gaussian latent tree model. This description consists of polynomial equations and inequalities involving covariances between the observed variables. Testing inequality constraints can be done using the inverse Wishart distribution and this leads to simple preliminary assessment of tree-compatibility. To test equality constraints we employ general techniques of tetrad analyses. This approach is effective even for small sample sizes and can be easily adjusted to test either entire models or just particular macrostructures of a tree. Our methods are simple to implement and do not require fitting of the model. The versatility of the techniques is illustrated by performing exploratory and confirmatory tetrad analyses in linguistic and biological settings respectively.

Some key words: Gaussian distribution; Latent tree model; Tetrad analysis; Tree constraint; Tree quartet.

1. Introduction
Modelling with hidden variables is common in the framework of graphical models (Lauritzen, 1996; Koller & Friedman, 2009). When the observed variables are the leaves of a tree and the unobserved variables are interior nodes, the model is called a latent tree model (Choi et al., 2011; Wang et al., 2008). Such models are used in domains including sociology, biology and linguistics (Eisenstein et al., 2010; Mourad et al., 2013; Zwiernik, 2016). Gaussian latent tree models lead to popular visualisation techniques when considering high-dimensional data (Lawrence, 2004).
Latent tree model selection techniques often presuppose that the data generating process is driven by some latent tree model, so the appropriateness of any such model is assessed only relative to other tree models. Knowing whether any latent tree model could adequately explain what is observed is pertinent in phylogenetic settings where, for example, the effect of a possible horizontal gene transfer (Hao & Golding, 2008) makes any underlying such model dubious.

By characterizing the covariance space related to Gaussian latent tree models, we can better assess the suitability of trees or the fit of a particular tree. In this paper we present the complete description of this model class by relating a particular model parameterization to the space of phylogenetic oranges (Engström et al., 2012; Gill et al., 2008; Kim, 2000; Moulton & Steel, 2004). Such a complete description had been known for a simple tree with only four leaves (Pearl & Xu, 1987, Theorem 2) or for a star tree (Bekker & de Leeuw, 1987). For a general tree, only the defining equations have been derived; see Sullivant (2008, Corollary 6.5).

Our method uses the description of Gaussian latent tree models in two scenarios. In the first we are interested in whether any latent tree model is a possible explanation for a given dataset. In the second we fix a latent tree model. In both scenarios the alternative hypothesis is the saturated model. We illustrate these methods in §5·3 where we perform an exploratory search across language trees and in §5·4 where we test whether a previously hypothesized phylogenetic tree fits data for certain yeast species. In both applications it is contentious whether the class of phylogenetic trees is appropriate. This is addressed directly in our analyses without first fitting the model.

Let \( Z = (Z_u)_{u \in U} \) be a random vector whose components are indexed by the vertices of an undirected tree \( T = (U, E) \) with edge set \( E \subseteq U \times U \). The tree \( T \) induces a Gaussian tree model \( N(T) \) for \( Z \), which is a Gaussian graphical model on \( T \) (Lauritzen, 1996, §5.2). For any two nodes \( u, v \in U \), let \( \text{ph}(uv) \) denote the set of edges on the unique path between \( u \) and \( v \) in this tree. Then the model \( N(T) \) is the collection of all multivariate normal distributions on \( \mathbb{R}^{|U|} \) for which \( Z_u \) and \( Z_v \) are conditionally independent given a subvector \( Z_C \) whenever the set \( C \subseteq U \setminus \{u, v\} \) contains a node on \( \text{ph}(uv) \). For three nodes \( u, v, w \in U \), the conditional independence of \( Z_v \) and \( Z_w \) given \( Z_u \) is equivalent to \( \rho_{vw} = \rho_{uw} \rho_{uv} \). It follows that a normal distribution with correlation matrix \( R = (\rho_{uv}) \) belongs to \( N(T) \) if and only if \( \rho_{uv} = \prod_{e \in \text{ph}(uv)} \rho_e \) for all \( u, v \in U \), where \( \rho_e = \rho_{uv} \) when \( e \) is the edge \( (u, v) \).

In this paper we study Gaussian latent tree models where we only observe the random variables associated with the tree’s leaves. We henceforth denote the set of leaves of this tree by \( V \) and associated leaf distributions as \( V \)-marginal distributions. A typical such evolutionary tree, of Romance languages, is displayed in Fig. 1, where the observable, extant languages are represented as its leaves.

**Definition 1.** The Gaussian latent tree model \( M(T) \) for the subvector \( X = (Z_v)_{v \in V} \) is the set of all \( V \)-marginal distributions of the distributions in \( N(T) \).
The parameterization of $M(T)$ is induced from the parameterization of $N(T)$ and is

$$
\rho_{ij} = \prod_{e \in \text{ph}(ij)} \rho_e, \quad i, j \in V.
$$

(1)

As the variances $\sigma_{uu}$ for $u \in U \setminus V$ never appear in this parameterization, without loss of generality, we can assume they are equal to 1.

2. **Semialgebraic description of the latent tree model**

2.1. **Tree metrics and phylogenetic oranges**

Let $T = (U, E)$ be a tree with leaf set $V \subseteq U$. Associate to each edge a nonnegative number $d_e$, which we interpret as the length of this edge. Then we can compute the distance between any two leaves $i, j \in V$ as $d_{ij} = \sum_{e \in \text{ph}(ij)} d_e$. It is easy to check that a collection of such distances for all pairs $u, v \in V$ forms a metric. The set of all metrics that arise in this way for all $T$ with leaves labelled by $V$ is called the space of tree metrics. We recall the following result.

**Theorem 1 (Buneman, 1974).** A collection of positive numbers $d_{ij}$ for $i, j \in V$ forms a tree metric if and only if for all, not necessarily distinct, $i, j, k, l \in V$ we have $\max(d_{ik} + d_{jl}, d_{il} + d_{jk}) \geq d_{ij} + d_{kl}$. Equivalently, for any three sums $d_{ik} + d_{jl}, d_{il} + d_{jk}, d_{ij} + d_{kl}$, two are equal and not less than the third. Moreover, if the tree metric inequalities hold, then generically $T$ is uniquely identified.

In Theorem 1 the term generically means that the statement holds outside a set of measure zero corresponding to the vanishing of some edge lengths $d_e$. A more precise statement is possible if we allow semi-labelled trees; see *Semple & Steel* (2003, § 7). A careful analysis shows that this generic tree is always binary, i.e., all its inner nodes have degree three. The triangle inequality follows from setting $i, j, k$ distinct and $k = l$ in Theorem 1, which in turn implies that every tree metric is a metric on $V$.

**Corollary 1.** The space of tree metrics on a fixed tree $T$ is the set of all metrics on $V$ such that for any four distinct leaves $i, j, k, l$ such that $\text{ph}(i, j) \cap \text{ph}(k, l) = \emptyset$, $d_{ik} + d_{jl} = d_{il} + d_{jk} \geq d_{ij} + d_{kl}$.

Recall that $\text{ph}(i, j)$ is the set of edges and hence, for example, for a star tree any four leaves $i, j, k, l$ satisfy $\text{ph}(i, j) \cap \text{ph}(k, l) = \emptyset$. The condition $\text{ph}(i, j) \cap \text{ph}(k, l) = \emptyset$ implies that the induced subtree over $i, j, k, l$, that is, the smallest connected subgraph of $T$ containing $i, j, k, l$, is a quartet tree as in Fig. 2(a). This also explains the conditions of Corollary 1.

Another closely related space defined over a tree is the space of phylogenetic oranges (*Kim*, 2000; *Moulton & Steel*, 2004). For a fixed tree $T$ this is the same parameterization (1) as the Gaussian latent tree model but where the edge correlations $\rho_e$ are non-negative. The set of all points in $\mathbb{R}^{m(m-1)/2}$ that arise in this way is denoted $\text{PO}(T)$ and it forms a toric cube as defined in *Engström et al.* (2012). The union of all $\text{PO}(T)$ is denoted by $\text{PO}(V)$.

Let $\text{PO}_+(T)$ and $\text{PO}_+(V)$ respectively denote the subsets of $\text{PO}(T)$ and $\text{PO}(V)$ for which all coordinates are strictly positive; thus the corresponding edge correlations $\rho_e$ must be strictly positive. The space of tree metrics on a fixed tree $T$ is isomorphic to $\text{PO}_+(T)$, with the isomorphism given by $d_{ij} = -\log \rho_{ij}$. 

Downloaded from https://academic.oup.com/biomet/article-abstract/103/3/531/1744266 by guest on 29 July 2018
Theorem 2. Let $R = (\rho_{ij})_{i,j \in V}$ and suppose that $\rho_{ij} \geq 0$ for all $i, j \in V$. Then:

(a) $R \in \text{PO}(V)$ if and only if for every four not necessarily distinct elements $i, j, k, l$ in $V$, at least two out of three products $\rho_{ik}\rho_{jl}, \rho_{ij}\rho_{jk}, \rho_{ij}\rho_{kl}$ are equal and less than or equal to the third. Moreover, if this holds then $T$ with the property $R \in \text{PO}(T)$ is generically identified uniquely;

(b) for a fixed $T$, the space $\text{PO}(T)$ has dimension $|E|$. This is described by the following set of constraints. For any four distinct elements $i, j, k, l$ of $V$ such that $\text{ph}(i, j) \cap \text{ph}(k, l) = \emptyset$, $\rho_{ik}\rho_{jl} = \rho_{il}\rho_{jk} \leq \rho_{ij}\rho_{kl}$. Moreover, for any three distinct leaves $i, j, k$, the triangle inequality $\rho_{ij}\rho_{ik} \leq \rho_{jk}$ holds.

2.2 Latent tree models and phylogenetic oranges

We are now ready to derive the semialgebraic description of the model $M(T)$. Let $S_+(V)$ denote the space of all symmetric positive definite $|V| \times |V|$-matrices.

Theorem 3. Let $T$ be a tree and let $R = [\rho_{ij}] \in S_+(V)$ be a correlation matrix. Then $R \in M(T)$ if and only if $R' = [|\rho_{ij}|] \in \text{PO}(V)$ and $\rho_{ij}\rho_{ik}\rho_{jk} \geq 0$ for any three distinct $i, j, k \in V$.

The proof is given in the Appendix.

Example 1. Let $T$ be the tripod tree in Fig. 2(b). The space of correlation matrices in $M(T)$ is described by the inequalities

$$
\rho_{12}\rho_{13}\rho_{23} \geq 0, \quad |\rho_{12}\rho_{13}| \leq |\rho_{23}|, \quad |\rho_{12}\rho_{23}| \leq |\rho_{13}|, \quad |\rho_{13}\rho_{23}| \leq |\rho_{12}|.
$$

If $\rho_{12}, \rho_{13}, \rho_{23} \geq 0$ then by Theorem 2(b) the space described by the above inequalities corresponds to $\text{PO}(T)$. There are three other sign patterns for $\rho_{12}, \rho_{13}, \rho_{23}$ that ensure that $\rho_{12}\rho_{13}\rho_{23} \geq 0$. For every such pattern we obtain a copy of $\text{PO}(T)$. Quite remarkably, the space of the correlation matrices in $M(T)$ looks exactly like the three-dimensional slice of the corresponding binary latent class model; see Allman et al. (2015, Fig. 1). Such constraints cannot, in general, be neglected. For example, simple calculations show that the ratio of the volume of $M(T)$ to the volume of all $3 \times 3$ correlation matrices is only $2/\pi^2 \approx 0.2$.

Based on Theorem 2(b) and Theorem 3 we formulate the following result.

Proposition 1. If $T$ is a fixed tree then the space $M(T)$ has dimension $|V| + |E|$. Let $\Sigma$ be a covariance matrix with no zeros. Then $\Sigma \in M(T)$ if and only if for any three distinct leaves $i, j, k$,

$$
(\sigma_{kk}\sigma_{ij} - \sigma_{ik}\sigma_{jk})(\sigma_{jj}\sigma_{ik} - \sigma_{ij}\sigma_{jk})(\sigma_{ii}\sigma_{jk} - \sigma_{ij}\sigma_{ik}) \geq 0,
$$

and for any four distinct elements $i, j, k, l$ of $V$ such that $\text{ph}(i, j) \cap \text{ph}(k, l) = \emptyset$,

$$
\frac{\sigma_{ik}\sigma_{jl}}{\sigma_{ij}\sigma_{kl}} = \frac{\sigma_{il}\sigma_{jk}}{\sigma_{ij}\sigma_{kl}} \leq 1.
$$

Fig. 2. (a) A quartet tree $i|jk$. (b) Tripod tree.
This full algebraic and semialgebraic description can be viewed as a generalization of the main results in Bekker & de Leeuw (1987) and Pearl & Xu (1987) from star trees to general trees. An analogous description of the second order moments for binary latent tree models was given in Zwiernik & Smith (2011). The similarity of both descriptions arises because the parameterization of correlations in the binary latent tree model is precisely (1); see Zwiernik & Smith (2011, Lemma 4.1).

3. Using semialgebraic constraints

We now describe how the semialgebraic constraints can be used to give an indication of tree-compatibility. Here the constraints in (2), which hold for every tree topology, will be called tree-compatibility constraints. A test based on these constraints can be used as an effective preliminary assessment tool to inform whether it is legitimate to proceed to a more complex tetrad analysis as described in § 5. For a fixed $T$ we can further extend our test by including the inequality constraints in (3). The resulting constraints are called $T$-compatibility constraints. A test of fit based on such constraints is called a tree-compatibility or $T$-compatibility test as appropriate.

A straightforward but effective assessment of $T$-compatibility constraints can be obtained from the posterior probabilities by applying an inverse Wishart prior on the sample covariance. If $\hat{\Sigma}$ is a sample covariance matrix based on a sample $X$ of size $n$ from $N_m(0, C)$, then the estimated scatter matrix is calculated as $S = n\hat{\Sigma} = XX^T$, where $X^T$ is the transpose of $X$, which is Wishart distributed, $S \sim W_m(n, C)$ (Wishart, 1928). A common prior distribution for unknown covariance $C$ is inverse Wishart, $W_m^{-1}(n_0, C_0)$, e.g., Gelman et al. (2013), Carlin & Louis (2008) and Roverato (2002). The inverse Wishart prior is conjugate, so the posterior density $p(C \mid X)$ is inverse Wishart $W_m^{-1}(n_0 + n, C_0 + S)$. As in Roverato (2002), for $C_0$ the identity matrix $I_{|V|}$ can be used and letting $n_0 = m$ ensures that the inverse Wishart prior density has a valid number of degrees of freedom. Then covariance matrices can be sampled from the conditional distribution of $C$ given $X$ and each draw standardized to form a correlation matrix and then tested against the constraints. After $N$ such draws from the posterior distribution, an estimate of the posterior probability that $C$ satisfies the positivity constraint can be obtained. Of course other choices of families of priors could be chosen instead, for example the scaled inverse Wishart distribution (O’Malley & Zaslavsky, 2008), or we could use a strategy that models correlation and covariance separately (Barnard et al., 2000). However, these alternatives bring additional computational cost and complexity. An entirely different approach focusing on Bayesian methods could involve adapting the work on inequality-constrained hypotheses to assess tree-compatibility, see Van de Schoot et al. (2012), Gu et al. (2014) and Gardner et al. (2014).

In Example 1, an estimate of the probability of $C$ satisfying the semialgebraic structure of $M(T)$ can be constructed using indicator functions. For each draw $l$ from the relevant inverse Wishart posterior distribution for $\hat{\Sigma}$, the following identity is evaluated:

$$r_{123}'(\hat{\Sigma}) = I\{(\bar{\sigma}_{33}\bar{\sigma}_{12} - \bar{\sigma}_{13}\bar{\sigma}_{23})(\bar{\sigma}_{22}\bar{\sigma}_{13} - \bar{\sigma}_{12}\bar{\sigma}_{23})(\bar{\sigma}_{11}\bar{\sigma}_{23} - \bar{\sigma}_{12}\bar{\sigma}_{13}) \geq 0\}$$

where $\bar{\sigma}_{ij}$ ($i, j = 1, 2, 3$) are the covariances corresponding to covariance draw $l$ of the posterior, the index $l$ being dropped for simplicity. The posterior probability of tree-compatibility is thus estimated using

$$R_{123}(\hat{\Sigma}) = \frac{1}{N} \sum_{l=1}^{N} r_{123}'(\hat{\Sigma}). \quad (4)$$
For a tree with four variables such that \(\text{ph}(1, 2)\) and \(\text{ph}(3, 4)\) do not intersect, the remaining test associated with the inequality constraints is

\[
R_{12|34}(\hat{\Sigma}) = \frac{1}{N} \sum_{l=1}^{N} \mathbb{I}\{\hat{\sigma}_{14}\hat{\sigma}_{23} - \hat{\sigma}_{12}\hat{\sigma}_{34} \leq 0\}\mathbb{I}\{\hat{\sigma}_{13}\hat{\sigma}_{24} - \hat{\sigma}_{12}\hat{\sigma}_{34} \leq 0\} \prod_{1 \leq i < j}^{} \prod_{< k < l}^{} r^{ij}_{lk}(\hat{\Sigma}).
\]

These sampling approaches do not extend to the algebraic constraints because the set of draws from the posterior satisfying an equality constraint will have zero probability. Thus an alternative approach is needed that uses sample distributions of the minors of a covariance matrix.

4. The sample distribution of algebraic constraints

From §3 and Theorem 2(b), the signs of tetrad constraints \(\sigma_{ik}\sigma_{jl} - \sigma_{ij}\sigma_{kl}\) and other quadratic binomials of the form \(\sigma_{ij}\sigma_{jk} - \sigma_{ij}\sigma_{ik}\) provide essential information about whether a Gaussian distribution lies in \(M(T)\). These types of constraints can be realized as minors of the covariance submatrix \(\Sigma\), that is \(\text{det}(\Sigma_{ij,kl})\) and \(\text{det}(\Sigma_{ij,ik})\) where \(\Sigma_{ij,kl}\) denotes the \(2 \times 2\) submatrix of \(\Sigma\) with rows \(i\) and \(j\) and columns \(k\) and \(l\). Let \(\mathcal{M}_2\) denote the set of all subsets of \([1, \ldots, m]\) of cardinality two. We now propose the following estimator of the value of \(\text{det}(C_{I,J})\) for \(I, J \in \mathcal{M}_2\),

\[
Q_{I,J} = \frac{1}{n(n-1)} \text{det}(\mathcal{S}_{I,J}).
\]

We note from Drton et al. (2008, Corollary 4.2) that \(Q_{I,J}\) is an unbiased estimator of \(\text{det}(C_{I,J})\).

In what follows we provide the covariances between different \(Q_{I,J}\). For an \(m \times m\) matrix \(A\), let \(A^{(2)}\) denote the matrix with rows and columns indexed by elements \(\mathcal{M}_2\) whose \((I,J)\)th element is the corresponding minor \(\text{det}(A_{I,J})\). With this notation, the matrix whose elements are the estimators \(Q_{I,J}\) is \(S^{(2)}/n(n-1)\).

There is no simple explicit formula for covariances of various 2-minors, but they can be computed if the true distribution \(C\) is known. From Drton et al. (2008, Proposition 3.3),

\[
\text{cov}(S^{(2)}) = (C^{1/2})(2) \otimes (C^{1/2})(2) \text{cov}(W^{(2)})(C^{1/2})(2) \otimes (C^{1/2})(2),
\]

where \(W\) has the standard Wishart distribution \(\mathcal{W}_m(n, I)\) and \(\otimes\) is the Kronecker product.

In the rest of this section we provide a complete description of the covariance matrix \(\text{cov}(W^{(2)})\). Our discussion follows Drton et al. (2008, Example 4.6). This gives the same derivation for the case \(m = 4\). We show below that the generalization to \(m \geq 4\) is straightforward.

The matrix \(\text{cov}(W^{(2)})\) has many symmetries that we want to exploit. For all \(I, J \in \mathcal{M}_2\),

\[
\text{det}(W_{I,J}) = \text{det}(W_{J,I}),
\]

\[
\text{cov}\{\text{det}(W_{I,J}), \text{det}(W_{K,L})\} = \text{cov}\{\text{det}(W_{J,I}), \text{det}(W_{K,L})\} = \text{cov}\{\text{det}(W_{K,L}), \text{det}(W_{I,J})\}.
\]

We can therefore, without loss of generality, consider only unordered pairs of sets \((I, J)\), where \(I = \{i, j\}\) and \(J = \{k, l\}\) with \(i < j, k < l\) and either \(i < k\) or \(i = k\) and \(j \leq l\).

Let \(A \Delta B = (A \setminus B) \cup (B \setminus A)\) be the symmetric difference of two sets. We split the rows and the columns of \(\text{cov}(W^{(2)})\) into blocks according to the values of \(I \Delta J\) and \(K \Delta L\). With this convention, by Drton et al. (2008, Corollary 4.2 and Proposition 3.4), \(\text{cov}(W^{(2)})\) is a block-diagonal matrix. Therefore, it is enough to describe its diagonal blocks. Since \(|I \Delta J| \in \{0, 2, 4\}\), we have
three types of blocks. We first describe the block corresponding to \( I \Delta J = K \Delta L = \emptyset \), or equivalently \( I = J, K = L \). This block forms a \( m(m-1)/2 \times m(m-1)/2 \)-matrix that satisfies:

\[
\text{cov}\{\det(W_{I,I}), \det(W_{K,K})\} = \begin{cases} 
0, & |I \cap K| = 0, \\
2n(n-1)^2, & |I \cap K| = 1, \\
2n(2n+1)(n-1), & I = K.
\end{cases}
\]

We now have \( m(m-1)/2 \) blocks corresponding to \( I \Delta J = K \Delta L = \{i, j\} \) for \( 1 \leq i < j \leq m \). Every such block is an \((m-2) \times (m-2)\) matrix, where \( I = \{i, k\}, J = \{j, k\}, K = \{i, l\}, L = \{j, l\} \) for some \( k \leq l \in \{1, \ldots, m\}\backslash \{i, j\} \). All of these matrices have two types of elements. The diagonal entries, \( k = l \), equal \( n(n+2)(n-1) \). The off-diagonal elements, \( k < l \), up to a sign, are \( n(n-1)^2 \). The sign depends on the relative order of \( i, j, k, l \). By Drton et al. (2008, Theorem 4.5), the sign is positive if \( k < i < j < l \). Now a simple sign analysis shows that the sign is negative only if either \( i < k < j < l \) or \( k < i < l < j \). This yields

\[
\text{cov}\{\det(W_{ik,jk}), \det(W_{il,ji})\} = \begin{cases} 
n(n+2)(n-1), & k = l, \\
-n(n-1)^2, & i < k < j < l \text{ or } k < i < l < j, \\
n(n-1)^2, & \text{otherwise}.
\end{cases}
\]

Finally, there are \( m(m-1)(m-2)(m-3)/24 \) blocks corresponding to \( I \Delta J = \{i, j, k, l\} \), where \( 1 \leq i < j < k < l \leq m \). Each such block is a \( 3 \times 3 \) matrix of the form

\[
\begin{bmatrix}
ij, kl & ik, jl & il, jk \\
\cdot & a & b \\
\cdot & \cdot & a
\end{bmatrix}
\]

where \( a = 2n(n-1) \) and \( b = n(n-1) \).

5. QUARTETS AND APPLICATIONS OF TETRAD ANALYSES

5.1. The method of quartets

For any four distinct leaves \( i, j, k, l \in \mathcal{V} \) we say that \( d_{ij, kl} = ij|kl \) forms a quartet of \( \mathcal{T} \) if the paths \( \text{ph}(i, j) \) and \( \text{ph}(k, l) \) are disjoint, cf. Fig. 2(a). A binary tree \( \mathcal{T} \) displays the set of quartets \( \mathcal{Q} \) if each quartet \( q \in \mathcal{Q} \) is a quartet of \( \mathcal{T} \). A set of quartets \( \mathcal{Q} \) is said to determine \( \mathcal{T} \) if \( \mathcal{T} \) displays \( \mathcal{Q} \) and \( \mathcal{T} \) is the unique tree displayed by \( \mathcal{Q} \) (Semple & Steel, 2003); the set of all quartets displayed by \( \mathcal{T} \) is denoted by \( \mathcal{Q}_\mathcal{T} \). Quartets can be considered to be fundamental components of binary trees; see Dress et al. (2012) for more details. A set \( \mathcal{Q}_\mathcal{T} \) is said to be minimal if there exists no element \( q \in \mathcal{Q}_\mathcal{T} \) such that \( \mathcal{Q}_\mathcal{T} \backslash \{q\} \) determines \( \mathcal{T} \). Grünewald et al. (2008, Theorem 2.4) provides the minimum size of any \( \mathcal{Q}_\mathcal{T} \), i.e., the size of the smallest minimal defining quartet set, which for a binary tree is just the number of internal edges of \( \mathcal{T} \). Furthermore, Semple & Steel (2003, Theorem 6.8.8) provide a quick method for constructing minimal defining sets of quartets that define binary phylogenetic trees.

Let \( \mathcal{V} \subset \mathcal{U} \) be such that \( \mathcal{V} = \{i, j, k, l\} \), where these elements are distinct. Consider three random variables \( Q_{ik,jl}, Q_{il,jk} \) and \( Q_{ij,kl} \) as defined in (5). By Theorem 2, if a tree model holds, then the mean of one of the three will be zero and the other two means will be equal up to sign. So these \( Q_{I,J} \) can be used to test the algebraic constraints in Proposition 1.
Here we focus on testing the vanishing tetrads, i.e., testing whether the quartet $q_{ij,kl}$ is displayed in $T$ given the data. To test a particular binary tree $T$, a set $Q_T$ is required, i.e., a set of quartets $Q$ that determines $T$. The number of edges of $T$ is $2m - 3$ and so the Gaussian latent tree model on $T$ has codimension $m(m - 1)/2 - (2m - 3)$. This means that to test a model, we need to work with quartet systems $Q_T$ of size quadratic in $m$. On the other hand if we believe that the data come from a latent tree model, then to only find the corresponding tree $T$ we can work with any minimal quartet system determining $T$, and these are of size $m - 3$, the number of internal edges. This makes a big difference for larger trees.

In practice, one may wish to select $Q_T$ such that it is minimal of size $m(m - 1)/2 - (2m - 3)$, i.e., it contains no redundant quartets, because otherwise the covariance of minors matrix may be close to being singular; see Bollen & Ting (1993). However, there may be no obvious reason to consider the corresponding $Q_{ij,kl}$ as in (5) and define $Q_T = [Q_{ij,kl}]$ to be the vector of these $Q_{ij,kl}$. We write $\hat{Q}_{ij,kl}$ for the sample means of the observations of $Q_{ij,kl}$. Since $\hat{Q}_T$ is a consistent estimator of $Q_T$ (Drton et al., 2007), as the sample size $n$ tends to infinity any tree $T$ is uniquely identified by the $i$, $j$, $k$, $l$ such that $E(\hat{Q}_{ij,kl}) = 0$.

To standardize the data we use the sample covariance matrix $\hat{\Sigma}_{Q_T}$, which has dimension $p = |Q_T|$, or we can use its proxy $\hat{\Sigma}_{Q_T}$, obtained by recycling $\text{cov}(W^{(2)})$ computed in § 4 and replacing $C$ in (6) with the sample covariance of original variables $\hat{\Sigma}$. The matrix $\hat{\Sigma}_{Q_T}$ can be obtained much more efficiently than $\hat{\Sigma}_{Q_T}$. An appropriate simultaneous test statistic (7) is provided in Bollen & Ting (1993),

$$\mathcal{T} = \hat{Q}_T^T \hat{\Sigma}_{Q_T}^{-1} \hat{Q}_T. \quad (7)$$

As $\mathcal{T}$ is constructed with $p$ algebraically independent quartets, its asymptotic distribution is $\chi^2_p$. Compare (7) with Bollen & Ting (1993, (20)) where their $\Sigma_{tt}$ is the covariance of $n^{1/2}\hat{Q}_T$. Here the sample size $n$ is incorporated implicitly through $\hat{\Sigma}_{Q_T}^{-1}$ so (7) provides a significance test for the equality constraints in (3), where the required moments of $Q_{i,j}$ are given in § 4. This provides a quick method for assessing whether a Gaussian dataset appears consistent with the algebraic constraints associated with any tree model.

In deriving the asymptotic distribution of (7) we implicitly assume that the true covariance matrix is a sufficiently regular point of the given tree model. In practice, it is enough to assume that the true covariance matrix contains no zeros; see Drton et al. (2016a) and Drton et al. (2016b, § 5).

Hypothesis testing for vanishing tetrads can be used for both confirmatory tetrad analysis and for exploratory tetrad analysis. There are many algorithms for obtaining candidate trees, for instance see Junker & Schreiber (2011) and Sung (2009) for surveys of methods. However, often there is no way to assess the suitability of the final tree. Confirmatory tetrad analysis takes a candidate tree and provides an absolute rather than relative value as to how well the data support the purported tree.

In the case of a large tree it is infeasible to test all quartets at once, but it is straightforward and very stable to test single quartets or a small subset of them. One advantage of this approach is that it allows us to identify easily certain macrostructures of the tree which may lead to more robust techniques for finding the underlying tree. We now illustrate confirmatory and exploratory techniques for simulated data and some linguistics datasets.
Fig. 3. Illustration of the simulations in §5.2. One hundred observations are generated from a random matrix in the tree model for the quintet tree 12|5|34 and the corresponding test statistic is computed. This procedure is repeated 10,000 times. In each panel we compare the sample distribution of a test statistic against its theoretical distribution. In (a) we test a single tetrad 12|34. In (b) we test a single false tetrad 13|24. In (c) we test two tetrads 12|35, 15|34, and in (d) we test a minimal set of quartets defining the true quintet tree. The solid lines are densities of $\chi^2_1$, $\chi^2_1$, $\chi^2_2$, and $\chi^2_3$ respectively.

5.2. Basic simulations for the method of quartets

In this section we provide a basic analysis of the methods discussed in the previous section. The only difference from the previous applications of this method in other contexts is that in (7) we explicitly replaced the sample covariance of the tetrads with $\hat{\Sigma}_{Q_T}$ as explained in §5.1. The data in our simulations come from the quintet tree model 12|5|34; cf. Fig. 1.

We first randomly choose the true covariance matrix $C$ by sampling the edge correlations uniformly from the interval $[1/2, 1]$. Given this random true covariance matrix, we can now repeat the following evaluation procedure 10,000 times. We sample $n = 100$ points from the given distribution $C$. In this scenario, standard packages that might be used to find the maximum likelihood estimate, such as the sem package (Fox et al., 2014; R Development Core Team, 2016), are unstable. On the other hand any set of quartets can be easily tested, without fitting the model. Moreover, the sample distribution of the test statistic is already very close to the asymptotic distribution, even when the sample size is only about twice the dimension of the model, though of course the power of the test will then be much lower.

In Fig. 3 we compare simulated values of test statistics of the form (7) with their asymptotic distributions. Figure 3(a) depicts the statistic built on a single tetrad constraint for the quartet 12|34. This constraint holds for the data-generating distribution and therefore the test statistic should have asymptotic $\chi^2_1$ distribution. The histogram is very close to the theoretical distribution. For comparison, Fig. 3(b) shows the sample distribution of the same test statistic for the quartet 13|24. This constraint does not hold for the data-generating distribution and the sample distribution of the corresponding test statistic is very far from $\chi^2_1$. The test statistic can easily be set up for any subset of quartets. In Fig. 3(c) we plot the test statistic to test two quartets 12|35...
and 15|34. This is the minimal set of quartets that identifies the quintet tree 12|5|34. This means that these two particular quartets will not be simultaneously satisfied for any other tree model. Again, the sample distribution lies very close to the asymptotic $\chi^2$ distribution.

In Fig. 3(d) we test simultaneously a minimal set of quartets 12|34, 12|35, 15|34 defining the quintet tree model. In this case the sample distribution of the test statistic also lies close to $\chi^2$ with a slightly smaller variance, because the true distribution is closer to a mixture of $\chi^2$-distributions; thus the test based on our statistic is typically more conservative. To obtain a better understanding of its performance we compare it with the structural expectation-maximization algorithm (Friedman et al., 2002) as applied to Gaussian latent tree models. This algorithm tries to find the tree that gives the maximum value of the likelihood function. However, like the standard expectation-maximization algorithm, it often gets stuck in a local maximum. In our simulations we generated 100 datasets from the given quintet model. If the sample size $n = 60$, then for our particular choice of a correlation matrix with all edge correlations equal to 0·7, we obtained the correct tree only 68 out of 100 times. On the other hand, our tetrad method always confirms the correct tree for any significance level smaller than 0·1. If $n = 200$ then the structural expectation-maximization algorithm was correct 99 out of 100 times, and again our quartet method was always correct. We emphasize that in a less ideal situation, for example, when some edge correlations are small, or in the presence of partial misspecification, the structural expectation-maximization algorithm will perform poorly because the likelihood function is less stable. In contrast, our computations show that the quartet method tends to be much more robust.

5.3. Exploratory tetrad analysis example: linguistics

Consider now the linguistic dataset from Shiers et al. (arXiv:1410.0813), which comprises phonetic functional spectrogram data from French, Italian, Portuguese, and two forms of Spanish, namely American and Iberian. Acoustic data have provided new insights into language development (Bouchard-Côté et al., 2013; Aston et al., 2010). Here the evolutionary dependencies between spoken numbers are studied, with each extant language treated as a leaf vertex. The high dimensional spectrogram data are projected from 8100 dimensions to 15 dimensions using a variant of canonical variate analysis, see Shiers et al. (arXiv:1410.0813). Each of the 15 canonical components projects the mean word data to obtain 15 new datasets referred to as canonical scores. Each canonical component accounts for a particular combination of phonetic variation and each set of canonical scores is considered independently. This gives us the flexibility to hypothesize different evolutionary relationships for different aspects of the speech. For each set of canonical scores a $5 \times 5$ covariance matrix is calculated between the five languages. Royston’s multivariate normality test (Royston, 1983) does not reject Gaussianity at the 0·01 level for any of these 15 sets of scores.

We sampled $10^5$ covariance matrices from the inverse Wishart posterior for each of the sample covariances $\hat{\Sigma}_1, \ldots, \hat{\Sigma}_{15}$. We then performed a tree-compatibility test with respect to the positivity constraint implied by the triangle inequalities in Theorem 2(b) for each canonical component. We identify four such components, the first, fourth, sixth, and second, with high posterior probabilities, respectively 1, 0·89, 0·77 and 0·74, which warrant further investigation.

For the quintet tree in Fig. 1, there are 15 different labelled binary trees to test. In order to test a particular configuration of labels we construct a set of minimal defining quartets $Q$ for the quintet tree as referenced in § 5·1; in the case of the quintet tree this smallest minimal defining set contains two quartets.

For each of the four dimensions of interest, using the sampling distributions given in § 4 and the test statistic (7) with two degrees of freedom, a $p$-value can be calculated for each of the
Correlation space of Gaussian latent tree models

15 non-isomorphic trees with languages as leaves. To retain an overall significance rate of less than 0.05 a Bonferroni correction (Dunn, 1961) is applied such that the significance level is set at 0.05/15 ≈ 0.0033 per test. If more than one tree is not rejected then the candidate tree proposed by exploratory tetrad analysis is that with the highest $p$-value. We find that multiple trees exceed the threshold for all four components. The highest $p$-values for the first, second, fourth and sixth components were 0.524, 0.960, 0.775 and 0.902 respectively relating to the candidate trees: 12|4|35, 13|5|24, 14|2|35, and 23|1|45 respectively with coding 1 = French, 2 = Italian, 3 = Portuguese, 4 = American Spanish, 5 = Iberian Spanish.

For illustration we focus on the candidate tree for the second component, which is displayed in Fig 1. It is known from the analysis and expert interpretation in Shiers et al. (arXiv:1410.0813) that this component is likely to relate to variation in vowel sounds, nasality, and the lip rounding of language speakers. By isolating these phonetic features and identifying a tree that fits the data we can gain insights which may have otherwise been obscured. For example, from this particular analysis we could hypothesize that the differences in nasality of Italian and French evolved independently conditional on the common ancestor of Spanish and Portuguese. In combination with expert judgement, such statements can provide good starting points for further analyses of these features in relation to a specified tree.

5.4. Confirmatory tetrad analysis example: biology

We next consider growth curves for five yeast species each observed in the same 96 environments, each species with at least two replicates. The growth was recorded at approximately six-minute intervals over a period of just over 26 hours. These species have been studied before (Marcet-Houben & Gabaldón, 2009) and a phylogeny has been suggested as in Fig. 4. However, Libkind et al. (2011) hypothesize that $S.\text{bayanus}$ is a hybrid involving $S.\text{cerevisiae}$. This alternative hypothesis would violate the tree assumption. Previous research has indicated that for the studied yeast species there is positive correlation between growth-related phenotypic variation and genotypic phylogenetic relationships, e.g., Liti et al. (2009) and Warringer et al. (2011). This leads us to consider the yeast growth-curve data to investigate evolutionary questions. We carried out a confirmatory tetrad analysis to assess whether the proposed tree structure in Marcet-Houben & Gabaldón (2009) was reflected in any aspects of the growth data.

To pre-process the data, a smoothed cubic spline basis was fitted to each growth vector, resulting in a set of functional data objects which were then regularly evaluated to obtain comparable discretized representations. Mean vectors were then calculated for each species and environment and then these were standardized to remove mean environmental effects. We then performed a principal component analysis across species to identify the core variability of the growth curves. The first four components account for over 99% of variability. More detailed analysis, not reported here, can help interpret these components. For example, the first component relates only to growth variation in hours 10 to 26, whereas the second component relates to growth variation peaking at 12 hours with opposite growth variation from 18 hours onwards.
For each of the mean species projections in these dimensions, the sample covariance matrix was constructed. As a first step, the inverse Wishart approach specified in (4) was implemented. Recall that the tripod constraints are tree-compatibility constraints and thus require no tailoring to a specific $T$. Hence, these can be used very simply to narrow the list of components to test as part of a confirmatory tetrad analysis. The tree-compatibilities for the first four components were 31%, 2%, 18%, and 3% respectively. Thus, we consider the first and third components worth investigating further via confirmatory tetrad analysis for $T$-compatibility.

The results of the confirmatory tetrad analysis for $T_5$-compatibility, see Fig. 4, gave $p$-values 0.721 and 0.955 for the first and third components. To double-check these results we repeated the test using the bootstrapping strategy outlined in Bollen & Stine (1992). The results were very similar, with $p$-values of 0.729 and 0.921 respectively. The confirmatory tetrad analysis and inverse Wishart simulation results both gave upper bounds on $T_5$-compatibility, but on balance we concluded that the first and third components were $T_5$-compatible. Therefore, the class of Gaussian latent tree models does appear suitable for modelling some aspects of these yeast species’ growth curves. However, for features relating to components 2 and 4, there is some evidence to support the exploration of a wider model class that could accommodate the hybrid hypothesis described in Libkind et al. (2011).

6. Discussion

Understanding the complete description of the correlation space associated with Gaussian latent tree models suggests a number of useful tools for assessing tree-compatibility either on a class basis or for a specified tree. Some of the methods described in this paper are particularly useful as part of an exploratory analysis for defining the relevant model search space, whereas others are ideal as a final check of the conclusions of a model search. The complete semialgebraic structure of the correlation space has not been used elsewhere for assessing tree-compatibility of data, though the positivity constraint has been used previously; see Shiers et al. (arXiv:1410.0813). Incorporating a prior such as the inverse Wishart and sampling from the posterior distribution allows probabilistic conclusions about the model. This provides a more nuanced answer than a simple assessment of inequalities via the plugging in of covariance point estimates, and enables two or more incompatible but plausible trees to be compared.

Although our results are focused on Gaussian models, they can be extended to more general scenarios. Gaussian tree models can be thought of as linear structural equation models with Gaussian errors. If the errors are instead non-Gaussian but with finite variance, the covariance matrices will still obey the same constraints as in the Gaussian models. This means that our procedure can be used for basic model assessment also for non-Gaussian data given the second order moments exist.

One important practical consideration is the scalability of these methods. Techniques employing the semialgebraic constraints can be adapted to a larger number of variables reasonably well. For a confirmatory tetrad analysis the biggest computational cost is the calculation of the covariance of minors, which for $p$ observed random variables has dimension of order $p^4$, and can become prohibitive. For example, if 8GB of RAM is allocated for a single matrix, the limit of $p$ is approximately 25 even if redundant rows and columns are removed from the matrix. However, much larger $p$ can be considered by calculating the relevant statistics for each quartet marginally. Then the covariance matrix of minors has dimension only 36 and the memory can be released once each quartet has been tested. In either case, the final memory requirement could further be reduced with programming that takes advantage of symmetries and sparseness. In a similar vein, to extend the scope of exploratory tetrad analysis to a greater number of variables,
one strategy is to only assess single quartets in the first instance and use these results to reduce the set of possible trees. Given the effectiveness of the quartet testing with even small sample sizes, this approach seems sensible and to have significant advantages over methods that require a whole model to be tested at once.

ACKNOWLEDGEMENT

We are grateful to both referees for comments that substantially improved the presentation of the paper. Nathaniel Shiers acknowledges the support of the Economic and Social Research Council. Piotr Zwiernik was supported by the European Union 7th Framework Programme. John Aston was supported by the Engineering and Physical Sciences Research Council. The authors wish to thank Pantelis Hadjipantelis for pre-processing the linguistic data, John S. Coleman for interpretation of the linguistic analysis, and Chris Knight for provision of the yeast data.

APPENDIX

Proofs

Proof of Theorem 2. Assume first that all correlations $\rho_{ij}$ are strictly positive, that is $R \in \text{PO}_+(V)$ or $R \in \text{PO}_+(T)$. We use the fact that $\text{PO}_+(V)$ is isomorphic to the space of tree metrics, whose constraints are given in Theorem 1 and Corollary 1. Translating these constraints via $d_{ij} = -\log \rho_{ij}$ gives exactly the constraints in the proposed theorem. These constraints describe a closed set, which is the smallest closed set containing $\text{PO}_+(V)$, so it is enough to show that the closure of $\text{PO}_+(T)$ is equal to $\text{PO}(T)$. This follows from the fact that $\text{PO}(T)$ is a toric cube and, by Engström et al. (2012, Theorem 1), every toric cube is equal to the closure of its interior. □

Proof of Theorem 3. If $R \in M(T)$ then each $\rho_{ij}$ has representation (1). Thus $|\rho_{ij}| = \prod_{e \in \text{ph}(ij)} |\rho_e|$ and hence $R'$ also lies in $\text{PO}(T)$. To show that $\rho_{ij} \rho_{ik} \rho_{jk} \geq 0$ consider the induced subtree over $i, j, k$, that is, the smallest connected subgraph of $T$ containing vertices $i, j, k$. This subtree necessarily has a unique vertex $v$ that lies on the intersection of paths $\text{ph}(ij), \text{ph}(ik)$ and $\text{ph}(jk)$. Moreover, by (1),

$$
\rho_{ij} \rho_{ik} \rho_{jk} = \prod_{e \in \text{ph}(ij)} \rho_e \prod_{e \in \text{ph}(ik)} \rho_e \prod_{e \in \text{ph}(jk)} \rho_e = \prod_{e \in \text{ph}(v)} \rho_e^2 \prod_{e \in \text{ph}(ij)} \rho_e^2 \prod_{e \in \text{ph}(jk)} \rho_e^2 \geq 0.
$$

To prove the reverse implication, we note that every correlation matrix in $\text{PO}(T)$ has, after permuting rows and columns, a block diagonal structure with strictly positive elements in each block. Consider first the case when all elements of $R$ are nonzero, that is, $R'$ has strictly positive entries. Distinguish one node in $V$ and label it as 1. Let $D$ be a diagonal matrix such that $D_{ii} = -1$ if $\rho_{ii} < 0$ and $D_{ii} = 1$ if $\rho_{ii} > 0$. If $R \in M(T)$ then also $\text{DRD}$ lies in $M(T)$ because $M(T)$ is invariant with respect to all diagonal transformations. Moreover, it holds that $R' = \text{DRD}$ because $D_{ii} D_{ii} \rho_{ii} = |\rho_{ii}|$ for all $i \in V \backslash \{1\}$ and $D_{ii} D_{jj} \rho_{ij} = |\rho_{ij}|$ for $i, j \in V \backslash \{1\}$. This last equality follows from our assumption that $\rho_{ii} \rho_{ij} \rho_{jj} \geq 0$ so that the sign of $\rho_{ii} \rho_{ij}$ is equal to the sign of $\rho_{ij}$. Now, since $R' \in \text{PO}(T) \subset M(T)$ and $R = \text{DRD}$ we also have that $R \in M(T)$. The analysis of the case when $R$ is block diagonal will be omitted. □
