(Dated: Submitted to Phys. Rev. Lett. on 17 April)

We report an experimental demonstration of a compiled version of Shor’s algorithm using four photonic qubits. We choose the simplest instance of this algorithm, that is, factorization of $N = 15$ in the case that the period $r = 2$ and exploit a simplified linear optical network to coherently implement the quantum circuits of the modular exponential execution and semi-classical quantum Fourier transformation. During this computation, genuine multiparticle entanglement is observed which well supports its quantum nature. This experiment represents a step toward full realization of Shor’s algorithm and scalable linear optics quantum computation.

Shor’s algorithm [1, 2] for factoring large numbers is arguably the most prominent quantum algorithm to date. It provides a way of factorizing large integers in polynomial time using a quantum computer, a task for which no efficient classical method is known. Such a capacity would be able to break widely used cryptographic codes, such as the RSA public key system [3, 4]. Experimental realization of Shor’s algorithm has been a central goal on a quantum computer with classical algorithm, prime factorization takes exponentially many operations, which quickly becomes intractable as $l$ increases. Shor’s algorithm, in contrast, offers a new powerful way to solve this problem in only polynomial time [1, 2]. The strategy for the quantum factoring of a composite number $N = pq$, with both $p$ and $q$ being odd primes, is as follows. First we pick a random number $a (0 < a < N)$ with no factor in common with $N$. Then we quantum compute the period $r$ of the modular exponential function (MEF): $f(x) = a^x \text{mod}N$, which is the smallest positive satisfying $a^r \text{mod}N = 1$. From this period $r$, at least one nontrivial factor of $N$ is given by the greatest common denominator (g.c.d.) of $a^{r/2} \pm 1$ and $N$ with probability greater than 1/2. Shor’s algorithm provided an efficient quantum circuit (see Fig. 1a) to find the period $r$. Generally two registers of qubits are used [1, 15]: the first register with $n = 2\lceil\log_2 N\rceil$ qubits and the second one with $m = \lceil\log_2 N\rceil$ qubits. Applying Hadamard (H) transformations on the first register which was initialized in the state $|0\rangle^\otimes n$, it becomes $2^{-n/2} \sum_{x=0}^{2^n-1} |x\rangle$, an equally weighted coherent superposition of all $n$-qubit computational basis. Then the MEF unitarily implements $a^x \text{mod}N$ on the second register when the first register is in state $|x\rangle$, giving

$$\frac{1}{\sqrt{2^n}} \sum_{x=0}^{2^n-1} |x\rangle |a^x \text{mod}N\rangle.$$  \hspace{1cm} (1)

The highly entangled state Eq. (1) exhibits what Deutsch called “massive quantum parallelism” [15, 16], as although the execution has run for only once, it entangles all the $2^n$ input value $x$ with the corresponding value of $f(x)$ in parallel. Next, the quantum Fourier transformation (QFT) is applied on the first register, yielding

$$\frac{1}{2^n} \sum_{y=0}^{2^n-1} \sum_{x=0}^{2^n-1} e^{2\pi i xy/2^n} |y\rangle |a^x \text{mod}N\rangle,$$  \hspace{1cm} (2)

where interference leads to peaks in the probability amplitudes for terms $|y\rangle$ with $y = c2^n/r$ (for integer $c$). Thus the period $r$ can be deduced with high probability [1]. The QFT on $2^n$ elements can be efficiently performed on a quantum computer with $O(n^2)$ gates.
Implementations of this algorithm, even for factorization of a small number, place a lot of challenging experimental demands, e.g., coherent manipulations of multiple qubits and creations of highly-entangled multiqubit registers. Here we aim to demonstrate the simplest instance of Shor’s algorithm, i.e., the factorization of 15. Quantum networks for evaluating the MEF have been designed which involve $O(n^3)$ operations \[13, 17\]. Since $a^x = a^{2^{x_0} \cdot 2^{x_{n-1}} \cdots 2^{x_1} a^{x_0}}$, the execution of MEF can be decomposed into a sequence of controlled multiplications.

A general purpose algorithm to factorize 15 would require at least $n = 8$, $m = 4$, thus total 12 qubits \[13\]. Several observations allow us to reduce the resources substantially for the purpose of a proof-of-principle demonstration. First we choose to implement the algorithm with $a = 11$, this was identified in [5] as the “easy” case. Since $a^2 \mod 15 = 1$, MEF can be simplified to multiplications controlled only by $x_0$, which can be implemented by two controlled-NOT (CNOT) gates \[18\]. A QFT then follows to read out the period $r$. Such a circuit is shown in Fig. 1b. We note there are two qubits in the second register which evolve trivially during computation and can thus be left out.

To demonstrate the circuit of Fig. 1b we use single photons as qubits, where $|0\rangle$ and $|1\rangle$ are encoded with the photon’s horizontal ($H$) and vertical ($V$) polarization respectively. The difficulty in implementing this circuit lies in the CNOT gates and conditional $\pi/2$-phase shift gate. Although such entangling gates are possible for photons in principle using measurement-induced nonlinearity \[7\], currently they are still experimentally expensive \[12, 19\]. Here we note that since the target qubits of the CNOT gates are always fixed at $|H\rangle$, so the gate could be realized in an easier and more efficient fashion. Such a CNOT gate use only a polarizing beam splitter (PBS) and a half-wave plate (HWP), through which an arbitrary control qubit $\alpha|H\rangle + \beta|V\rangle$ and the target qubit $|H\rangle$ evolve into $\alpha|H\rangle|H\rangle + \beta|V\rangle|V\rangle$ upon post-selection \[20\], that is, conditioned on that there is one and only one photon out of each output (see Fig. 1c).

Furthermore, the QFT circuit can also be implemented with a more efficient method. It was observed by Griffiths and Niu \[21\] that when immediately followed by measurements, the fully coherent QFT can be replaced by a semiclassical version that employs only single-qubit rotations conditioned on measurement outcomes. This eliminates the need for entangling gates and reduces the numbers of gates quadratically. Thus we finally arrive at the simplified linear optics MEF and QFT network in Fig. 1c. We note despite of these simplifications, our circuit suffices to demonstrate the underlying principles of this algorithm.

Now we proceed with the experimental demonstration. Our experimental set-up is illustrated in Fig. 2, where a pulsed ultraviolet laser passes through two $\beta$-barium borate (BBO) crystals to create two pairs of entangled photon \[22\]. We use polarizers to disentangle the photons and prepare them in the states $|H\rangle_i$ with $i$ denoting the spatial modes (see Fig. 1c). The photons pass through the HWPs and are superposed on the PBSs (see Fig. 2) to implement the necessary single- and two-qubit gates. To ensure good spatial and temporal overlap, the photons are spectrally filtered ($\Delta \lambda_{FWHM} = 3.2$ nm) and coupled by single-mode fibers \[23\].

How could one experimentally verify a valid demonstration of Shor’s algorithm? First let us see the theoretical predictions. After $a = 11$ is chosen, the first step of this algorithm, the MEF should evolve as \[(1/2) \sum_{x=0}^{3} |x\rangle|11^x \mod 15\rangle = (1/2)(|0\rangle|11\rangle + |1\rangle|11\rangle + |2\rangle|1\rangle + |3\rangle|11\rangle)\]. As we rewrite it in binary representation $|(000001) + |011011) + |100001) + |111011)\rangle/2$, it shows that a nontrivial Greenberger–Horne–Zeilinger (GHZ) \[24\] entangled state $|\psi\rangle = (1/\sqrt{2})(|0\rangle_2|0\rangle_3|0\rangle_4 + |1\rangle_2|1\rangle_3|1\rangle_4)$ is created between the two registers. For Shor’s algorithm as well as some others, multiqubit entanglement is a necessary condition if the quantum algorithm is to offer an exponential speed-up over classical computation \[6\]. In our experiment, as the photons pass through the MEF circuit, we first observe the Hong-Ou-Mandel type interference \[25\] of three photons in arms 2-3-4 (see Fig. 3b). Then, after fixing the delays at the zero positions, we ex-
spect to determine the fidelity of the three-photon GHZ state and detect its genuine entanglement. The fidelity is judged by the overlap of the experimentally produced state with the ideal one: \( F_\psi = \langle \psi | \rho_{\text{exp}} | \psi \rangle \). Here \( \rho \) can be decomposed as \( \rho = |\psi \rangle \langle \psi| = (1/2)[(|HHH\rangle \langle HHH| + |VVV\rangle \langle VVV|) + (1/4)(|XXX - XYY - YYX - YXY\rangle \langle XXX - XYY - YYX - YXY|)] \), where \( X \) and \( Y \) denote Pauli matrices \( \sigma_x \) and \( \sigma_y \) which correspond to measurements in basis \(|+\rangle = (1/\sqrt{2})(|H\rangle \pm |V\rangle)\) and \(|R/L\rangle = (1/\sqrt{2})(|H\rangle \pm i|V\rangle)\) respectively. Figure 3c-3d shows the measurement results, which yield \( F_\psi = 0.74 \pm 0.02 \). It is proved that a fidelity above 50% is sufficient to show genuine entanglement of the GHZ states [28]. Thus the presence of genuine entanglement created between the two registers of our quantum computer is confirmed by 12 standard deviations.

Now we move to the next step—execution of the semiclassical QFT, as illustrated in Fig. 1c. We measure all possible correlations in the state of the qubits 1 and 2, which is the simplest way to simulate feedforward as used in Ref. 13. In the case photon 1 is measured in the state \(|1\rangle\), an additional quarter wave plate is inserted in the arm 2 to implement the \( \pi/2 \) rotation. Each measurement is flagged by a fourfold event where all four detectors fire simultaneously. The experimental results are shown in Fig. 4. With a probability of \( \sim 50\% \) the output is in \(|00\rangle\) corresponding to a failure. Another \( \sim 50\% \) probability yields \(|10\rangle\), which determines the period \( r = 2^2/2 = 2 \), thus g.c.d.(\( 11^2/2 \pm 1, 15 \)) = 3, 5, giving a successful factorization. To further quantitatively evaluate the performance, we use the squared statistical overlap [27] of experimental data with the ideal values, which is defined as \( \gamma = (\Sigma g=0 m_g 1/2 \cdot e_g 1/2)^2 \), where \( m_g \) and \( e_g \) are the measured and expected output-state probabilities of the state \(|g\rangle\), respectively. From the data in Fig. 4 we find \( \gamma = 0.99 \pm 0.02 \), indicating a near perfect experimental accuracy.

It is noticeable that the performance of the algorithm is considerably better than the quality of the entanglement created between the registers. The imperfections of our experiment mainly arise from high-order photon emissions and partial distinguishability of independent photons [28], which cause undesired mixtures in the GHZ state and degrade its fidelity. However, for the execution of the algorithm, such mixtures happen to have the same effect as the desired mixtures which could have been resulted from the ideal circuit anyway (after the qubits 2, 3, and 4 are entangled in the GHZ state, the qubit 2 is in a...
complete mixture tracing out of the qubit 3 and 4).

Some further remarks are warranted here. In this experiment we have used the simplified optical two-qubit PBS gates which are probabilistic and upon postselection [20], thus scalability is not directly implied in the present work. However, they can in principle be improved to be deterministic using the scheme by Knill et al. [7] given more photon source and complicated linear optics network. Furthermore, an alternative approach, known as the cluster-state model [29, 31] provides a more efficient realization of scalable photonic quantum computation [8, 13, 31]. In this model, universal quantum computation is achieved by single-qubit measurements on a prepared highly entangled cluster state.

Above we described a number of steps by which our MEF circuit was brought to a simpler form. While these steps may seem at first sight ad hoc, in fact they are an example of a general simplification method in the cluster state model. It has been shown that measurements of Pauli operator observables on cluster states transform the state via a set of simple (and computationally efficient) rules [30] to a cluster state with a different graphical description. Classical pre-processing can thus produce a cluster state implementation with a smaller number qubits, which, as demonstrated here, can simplify the experimental realization. Thus, our approach can be seen as a hybrid of cluster-state based and circuit-based models of quantum computation, adopting the most suitable model for the implementation of MEF and QFT circuits respectively.

In summary, we have completed a proof-of-principle demonstration of a compiled version of Shor’s algorithm using photonic qubits. Genuine multiparticle entanglement is observed during computation, which proves its unambiguous quantum nature. Our experiment presents an important step toward full realization of Shor’s algorithm and scalable linear optics quantum computation. To factorize larger numbers in the future, significant challenges ahead may include coherent manipulations of more qubits, constructions of complex multiqubit gates and quantum error correction [32].
