SUMMARY
This paper deals with the robust force and position control problems of series elastic actuators (SEAs). It is shown that an SEA’s force control problem can be described by a second-order dynamic model which suffers from only matched disturbances. However, the position control dynamics of an SEA is of fourth order and includes matched and mismatched disturbances. In other words, an SEA’s position control is more complicated than its force control, particularly when disturbances are considered. A novel robust motion controller is proposed for SEAs by using disturbance observer (DOb) and sliding mode control. When the proposed robust motion controller is implemented, an SEA can precisely track desired trajectories and safely contact with an unknown and dynamic environment. The proposed motion controller does not require precise dynamic models of environments and SEAs. Therefore, it can be applied to many different advanced robotic systems such as compliant humanoids, industrial robots and exoskeletons. The validity of the proposed motion controller is experimentally verified.

KEYWORDS: Control of robotic systems; Force control; Mechatronic systems; Sensor or actuator design; Compliant actuation.

1. Introduction
In the last two decades, series elastic actuators (SEAs) have received increasing attention due to their potential advantages (e.g., safety and high-fidelity force control) in physical robot–environment interaction.1–3 Several advanced robotic systems, such as compliant industrial, humanoid and exoskeleton robots, have recently been developed by using SEAs.4,5 A flexible mechanical component (e.g., spring) is intentionally placed between actuator and link in the design of an SEA.2,3 Although the compliant mechanical component improves physical robot–environment interaction, it complicates the mechanical design and motion control problem, particularly in position control.6,7 Moreover, it makes SEAs more sensitive to disturbances than inherently robust stiff actuators with high gear ratios. Therefore, the stability and performance of an SEA may significantly deteriorate by disturbances in practice.3,7,8

The position control problem of robots with flexible joints has long been studied in the literature. However, the proposed controllers have several shortcomings for SEAs. Singular Perturbation Method was applied to compliant robots in ref. [9]. This method is sensitive to disturbances, and it can...
only be applied if the joint stiffness is high enough. Compliant robots have generally been controlled by using a Proportional-Integral-Derivative (PID) controller combined with a model-based feed-forward controller. Although feed-forward control improves the positioning accuracy of controlled by using a Proportional-Integral-Derivative (PID) controller combined with a model-based control structures to be implemented in real time. Resonance ratio control (RRC) was originally proposed for the vibration control problem of industrial robots with flexible joints, and it was recently applied to SEAs in refs. [7, 16]. An RRC-based position controller is sensitive to load and link uncertainties as the robustness is degraded to suppress the vibration of link. Moreover, RRC cannot independently control whole system dynamics due to insufficient control parameters. Authors, for the first time, proposed the sliding mode control (SMC)-based robust position controller for SEAs in ref. [17].

SEA studies have generally focused on force/impedance control problem and its advanced robotic applications, for example, human–robot collaboration. A PID controller was proposed to perform force control in ref. [2]. The performance of force control was improved by applying feed-forward control signal with a model-based controller. The proposed force control method suffers from stability, slow response and overshoot problems due to neglected disturbances such as backlash and stiction. To tackle stability and performance problems, cascade force controllers (i.e., an inner-loop on motor velocity control and an outer-loop on force control) were proposed in refs. [3, 18, 19]. However, the proposed cascade force controllers are sensitive to disturbances. A high-order disturbance observer (DOb) was proposed for the inner-loop on motor velocity control so that the robustness of the force control system was improved in ref. [20]. Later, DOb-based robust force controller was applied to the University of Texas’ SEA (UT-SEA) and NASA’s compliant humanoid robot Valkyrie. In classical control, a high-order DOb synthesis is not straightforward, and it may significantly suffer from conservatism. Bae et al. reported the robust force controller’s unexpected stability problem and proposed an SMC force controller in ref. [23]. To suppress the chattering of the SMC force controller, Wang et al. proposed a modified SMC controller by using nonlinear DOb and high gain control in ref. [24]. Force control of an SEA was performed by using RRC in ref. [7]. However, tuning the control parameters of RRC is not easy in force control. Authors recently proposed a new motion controller for SEAs in ref. [25]. In this paper, an SEA’s force control problem is described by a fourth-order dynamic model which suffers from matched and mismatched disturbances. Another high-precision robust force controller was recently designed in ref. [26].

In this paper, a novel motion controller is proposed for SEAs. The position and force controllers are synthesized by combining DOb and SMC. The former not only improves the robustness by cancelling disturbances but also allows to reduce the control signal chattering and to deal with mismatched disturbances. It is noted that although the conventional SMC provides good robustness for matched disturbances, it is sensitive to mismatched disturbances. Therefore, the conventional SMC is not applicable for the position control problem of an SEA. Two continuous motion controllers are proposed by using Quasi-SMC and continuous SMC. The main drawbacks of continuous SMC control methods are the former degrades the robustness and the latter requires the estimation of acceleration. Continuous and discontinuous SMC methods are experimentally compared for SEAs in Section 5. An SEA’s dynamic model is derived by considering its position and force/impedance control applications. It is shown that a second-order dynamic model, which suffers from only matched disturbances, can be used to represent the force control problem of an SEA. However, the dynamics of the position control of an SEA is of fourth order and suffers from the mismatched disturbances in addition to matched disturbances. Therefore, an SEA’s robust position control is more complicated than its robust force control. The proposed robust motion controller provides high performance without requiring the precise dynamic models of an SEA and environment. For example, the link of an SEA can precisely track desired trajectories and stably contact with an unknown and dynamic environment. Therefore, the proposed controllers can be applied to different compliant robotic systems driven by SEAs, for example, exoskeletons, humanoids and collaborative industrial robots. Position and force control experiments are presented to validate the proposed sliding mode motion controller.

The organization of the paper is as follows: an SEA’s dynamic model is presented in Section 2; a second-order DOb is synthesized in Section 3; sliding mode motion controllers are synthesized in Section 4; the controllers are experimentally verified in Section 5; and conclusion is given in Section 6.
A sliding mode motion controller synthesis for SEAs

2. Series Elastic Actuators

In this section, an SEA’s dynamic model is derived for position and force/impedance control.

2.1. Position control

If an SEA does not physically interact with an environment (See Fig. 1(a)), then its dynamic model is

\[
\begin{align*}
J_n \ddot{q} + b_n \dot{q} &= \tau_n - \tau_d^m \\
J_m \ddot{\theta} + b_m \dot{\theta} &= \tau_m - \tau_s - \tau_n^m \\
\tau_n^m &= k^n (\theta - q)
\end{align*}
\]

where \(J_n\) and \(J_m\) are the nominal inertias of motor with speed reducer and link, respectively; \(b_n\) and \(b_m\) are nominal viscous friction coefficients; \(k^n\) is the nominal spring constant of the SEA; \(\theta\) and \(q\) are the angles of motor and link sides, respectively; \(\dot{\theta}\) and \(\ddot{\theta}\) are the first- and second-order derivatives of \(\theta\) (i.e., the speed and acceleration of the motor side); \(\tau_n\) is the applied torque at motor side; \(\tau_s\) is the nominal spring torque; \(\tau_d^m\) is the matched disturbance; and \(\tau_d^l\) is the mismatched disturbance.

The matched and mismatched disturbances of an SEA are

\[
\begin{align*}
\tau_d^m &= (J_m - J_n^m) \dot{\theta} + (b_m - b_n^m) \dot{\theta} + \tau_s - \tau_n^m + \tau_m^{ind} \\
\tau_d^l &= (J_l - J_n^l) \dot{\theta} + (b_l - b_n^l) \dot{\theta} + \tau_s + \tau_n^l - \tau_l^{ind}
\end{align*}
\]

where \(J_m\) and \(J_l\) are the uncertain inertias of motor with speed reducer and link, respectively; \(b_m\) and \(b_l\) are the uncertain viscous friction coefficients; \(k\) is the spring constant of the SEA; \(\tau_s = k (\theta - q)\) is the torque of the actuator’s spring; \(\tau_s\) is the gravitational disturbance; and \(\tau_m^{ind}\) and \(\tau_l^{ind}\) are unknown disturbances, respectively.

The position accuracy of an SEA’s link may significantly deteriorate by external load and various internal disturbances, such as nonlinear frictions and hysteresis, due to its complex mechanical design. To track the desired trajectory of an SEA’s link with high accuracy (e.g., \(q = q_{des}\)), \(\tau_d^m\) and \(\tau_d^l\) should be precisely suppressed/cancelled.

2.2. Force/impedance control

Let us describe force/impedance control goal of an SEA by using Hooke’s law:

\[
\tau_{s}^{des} = k (\theta - q)^{des}
\]

where \(\tau_{s}^{des}\) is the desired spring torque, and \((\theta - q)^{des}\) is the desired deflection of the actuator’s spring.
With a simple mathematical manipulation and assuming that \( q \) is known (i.e., the position of the SEA’s link is measured), Eq. (4) can be rewritten as follows:

\[
\theta_{des} = (1/k) \tau_i^{des} + q
\]  

(5)

where \( \theta_{des} \) is the desired \( \theta \).

Eqs. (4) and (5) show that force/impedance control of an SEA can be conducted by precisely controlling its motor position/angle (i.e., \( \theta = \theta_{des} \)).

When the link of an SEA interacts with an environment, its dynamic model is derived from Fig. 1(b) as follows:

\[
J_i^n \ddot{\theta} + b_i^n \dot{\theta} = \tau_i^n - \tau_{ext}^d
\]  

(6)

\[
\tau_{ext}^d = \tau_{ext}^d + J_e (\ddot{\theta} - \ddot{\theta}_e) + D_e (\dot{\theta} - \dot{\theta}_e) + K_e (\theta - \theta_e)
\]  

(7)

where \( \tau_{ext}^d \) is the external disturbance torque; \( \tau_{ext}^d \) is the applied external torque; \( J_e, D_e \) and \( K_e \) are the inertia, damping and stiffness of the environment which SEA physically interacts, respectively; and \( \theta_e \) is the position/angle of the environment.

To obtain a practical model for an SEA which physically interacts with an unknown environment, let us assume that \( \tau_{ext}^d \) and \( \tau_{ext}^d \) are unknown disturbances as shown in Fig. 1(b). If Eq. (6) is substituted into Eq. (1), then Eq. (8) is derived as

\[
J_m^n \ddot{\theta} + b_m^n \dot{\theta} = \tau_m - \tau_{ext}^d
\]  

(8)

where \( \tau_m^n = \tau_m + J_i^n \ddot{\theta} + b_i^n \dot{\theta} + \tau_i^n + \tau_{ext}^d \).

Eq. (8) is a second-order dynamic model of a servo system which is disturbed by matched disturbances. In many advanced robotic applications of SEAs, it is very hard to precisely model or measure the matched disturbances, for example, the dynamics of human beings in human–robot interaction and rehabilitation. Such disturbances may significantly degrade the stability and performance of an SEA’s force/impedance control if they are not treated in the controller synthesis. To perform force/impedance control, that is, to track the desired trajectory of the SEA’s motor with high accuracy (e.g., \( \theta = \theta_{des} \)), the matched disturbance \( \tau_{ext}^d \) should be precisely suppressed/cancelled.

3. Second-Order DOb

In this section, a second-order DOb is synthesized so as to estimate an SEA’s matched and mismatched disturbances and their first- and second-order time derivatives.

The state space representation of Eq. (1) is

\[
\dot{\xi} = A_n \xi + b_n \tau_m - \tau_{\text{dis}}
\]  

where

\[
A_n = \begin{bmatrix}
0 & 1 & 0 & 0 \\
-k^n/J_i^n & -b_i^n/J_i^n & k^n/J_i^n & 0 \\
0 & 0 & 0 & 1 \\
k_m^n/J_m^n & 0 & -k_m^n/J_m^n & -b_m^n/J_m^n
\end{bmatrix}, \quad \tau_{\text{dis}} = \begin{bmatrix}
0 \\
\tau_i^n \\
0 \\
\tau_m^n/J_m^n
\end{bmatrix},
\]

\[
b_n = \begin{bmatrix}
0 & 0 & 0 & 1/J_m^n
\end{bmatrix}^T
\]

and

\[
\xi = [q, \dot{q}, \theta, \dot{\theta}]^T.
\]

The second-order DOb is synthesized by assuming that disturbance vectors are bounded, that is, \( \| \tau_{\text{dis}} \| \leq \delta_{\tau_{\text{dis}}}, \| \dot{\tau}_{\text{dis}} \| \leq \delta_{\dot{\tau}_{\text{dis}}}, \| \ddot{\tau}_{\text{dis}} \| \leq \delta_{\ddot{\tau}_{\text{dis}}} \) and \( \| \dddot{\tau}_{\text{dis}} \| \leq \delta_{\dddot{\tau}_{\text{dis}}} \), where \( \| \cdot \| \) is the norm of \( \cdot \); \( \tau_{\text{dis}}, \dot{\tau}_{\text{dis}}, \ddot{\tau}_{\text{dis}} \) and \( \dddot{\tau}_{\text{dis}} \) are the first-, second- and third-order derivatives of \( \tau_{\text{dis}} \), respectively; and \( \delta_{\tau_{\text{dis}}}, \delta_{\dot{\tau}_{\text{dis}}}, \delta_{\dddot{\tau}_{\text{dis}}} \) and \( \delta_{\dddot{\tau}_{\text{dis}}} \) are real numbers.

In order to estimate \( \tau_{\text{dis}}, \dot{\tau}_{\text{dis}} \) and \( \dddot{\tau}_{\text{dis}} \), auxiliary variable vectors are defined by using

\[
z_1 = \tau_{\text{dis}} + L_1 \xi - z_2
\]  

(10)

\[
z_2 = \dot{\tau}_{\text{dis}} + L_2 \xi - z_3
\]  

(11)

\[
z_3 = \dddot{\tau}_{\text{dis}} + L_3 \xi
\]  

(12)

where \( z_j \in \mathbb{R}^4 \) is the \( j \)th auxiliary variable vector; and \( L_j \in \mathbb{R} \) is the \( j \)th control gain of DOb, yet to be tuned.
A sliding mode motion controller synthesis for SEAs

Time derivatives of Eqs. (10)–(12) are

\[ \dot{z}_1 = -(L_1 - L_2 + L_3) (z_1 + z_2) + z_2 + \ddot{\tau}_{\text{dis}} \]

\[ + (L_1 - L_2 + L_3) (A_0 \xi + b_n \tau_m + L_1 \xi) - (L_2 - L_3) \xi \]  
(13)

\[ \dot{z}_2 = -(L_2 - L_1) (z_1 + z_2) + z_3 - \ddot{\tau}_{\text{dis}} + (L_2 - L_3) (A_0 \xi + b_n \tau_m + L_1 \xi) - L_3 \xi \]

\[ \dot{z}_3 = -(L_3 (z_1 + z_2) + \ddot{\tau}_{\text{dis}} + L_3 (A_0 \xi + b_n \tau_m + L_1 \xi) \]  
(15)

where \( \dot{z}_j \in \mathbb{R}^4 \) is the time derivative of \( z_j \).

The dynamics of the auxiliary variable observer is

\[ \dot{\hat{z}}_1 = -(L_1 - L_2 + L_3) (\hat{z}_1 + \hat{z}_2) + \hat{z}_2 \]

\[ + (L_1 - L_2 + L_3) (A_0 \xi + b_n \tau_m + L_1 \xi) - (L_2 - L_3) \xi \]  
(16)

\[ \dot{\hat{z}}_2 = -(L_2 - L_1) (\hat{z}_1 + \hat{z}_2) + \hat{z}_3 + (L_2 - L_3) (A_0 \xi + b_n \tau_m + L_1 \xi) - L_3 \xi \]  
(17)

\[ \dot{\hat{z}}_3 = -L_3 (\hat{z}_1 + \hat{z}_2) + L_3 (A_0 \xi + b_n \tau_m + L_1 \xi) \]  
(18)

where \( \hat{} \) is the estimation of \( \bullet \). The second-order observer is synthesized by neglecting the estimation of \( \ddot{\tau}_{\text{dis}} \), that is, \( \ddot{\tau}_{\text{dis}} = 0 \).

Let us describe auxiliary variable estimation errors by using \( e_1 = z_1 - \hat{z}_1 \), \( e_2 = z_2 - \hat{z}_2 \) and \( e_3 = z_3 - \hat{z}_3 \). If Eqs. (3)–(15) are subtracted from Eqs. (16)–(18), then we obtain

\[ \dot{e}(t) = \Psi e(t) + \tau_d(t) \]  
(19)

where \( e(t) = \begin{bmatrix} e_1 \\ e_2 \\ e_3 \end{bmatrix} \), \( \Psi = \begin{bmatrix} -(L_1 - L_2 + L_3) I_4 & -L_1 - L_2 + L_3 & I_4 \\ -(L_2 - L_3) I_4 & -(L_2 - L_3) I_4 & I_4 \\ -L_3 I_4 & -L_3 I_4 & 0_4 \end{bmatrix} \), \( \tau_d(t) = [\ddot{\tau}_{\text{dis}} - \ddot{\tau}_{\text{dis}}]^T \), \( I_4 \) is a \( 4 \times 4 \) identity matrix and \( 0_4 \) is a \( 4 \times 4 \) null matrix.

The eigenvalues of \( \Psi \) correspond to the bandwidth of the observer and are derived by solving:

\[ \lambda (\Psi) = \det (\lambda I_{12} - \Psi) = (\lambda^3 + L_1 \lambda^2 + L_2 \lambda + L_3)^4 = 0 \]  
(20)

where \( \lambda \in \mathbb{C} \). The bandwidth of DOb is \( g_{\text{DOB}} \) rad/s when the control gains are \( L_1 = 3g_{\text{DOB}} \), \( L_2 = 3g_{\text{DOB}}^2 \) and \( L_3 = g_{\text{DOB}}^3 \).

One can easily adjust disturbance estimation dynamics by tuning the control gains of DOb, that is, assigning the eigenvalues of \( \Psi \). If the observer gains are properly tuned so that \( \Psi \) is negative definite, then input to state stability of Eq. (19) is achieved. In other words, all estimation errors which start in a circular plane whose radius is \( \|e(t_0)\| + \lambda_{\min}^{-1}(\Psi) \delta \dot{\tau}_{\text{an}} \) exponentially converge to a smaller circular plane whose radius is \( \lambda_{\min}^{-1}(\Psi) \delta \dot{\tau}_{\text{an}} \). The convergence rate and accuracy of estimation are simply improved by assigning larger eigenvalues to \( \Psi \), that is, using higher bandwidth \( g_{\text{DOB}} \) in the design of the observer. However, it cannot be freely increased due to practical constraints such as encoder resolution and sampling time. A DOb becomes more noise sensitive as its bandwidth is increased.

As \( e(t) \to 0 \), \( \dot{z}_1 \to z_1 \), \( \dot{z}_2 \to z_2 \) and \( \dot{z}_3 \to z_3 \). The estimations of disturbances and their successive derivatives are obtained by using Eqs. (10–12).

Since force control dynamics has only matched disturbances (See Eq. (8)), conventional, that is, zero order, DOb can be used in the robust force controller design.

4. Robust Motion Controller Synthesis

Sliding mode position and force controllers are designed for SEAs in this section. Continuous control signal is obtained by using two different methods, namely Quasi-SMC and continuous SMC. The stability of the proposed motion controllers is proved via Lyapunov’s second method.
4.1. Robust position controller synthesis

Eq. (1) can be rewritten by using

\[
\begin{align*}
\dot{x}_1 &= x_2 \\
\dot{x}_2 &= \frac{\nu}{J} x_3 - d_2 \\
\dot{x}_3 &= x_4 \\
\dot{x}_4 &= \frac{1}{J} \tau_m - d_4
\end{align*}
\] (21)

where \(x_1 = q\); \(x_2 = \dot{q}\); \(x_3 = \theta\); \(x_4 = \dot{\theta}\); \(d_2 = \frac{\nu}{J} x_1 + \frac{\nu}{J} x_2 + \frac{\nu}{J} \) is the mismatched disturbance in the second channel; and \(d_4 = \frac{\nu}{J} (x_3 - x_1) + \frac{\nu}{J} x_4 + \frac{\nu}{J} \) is the matched disturbance in the control input channel, that is, the fourth channel.

The trajectory tracking error of the actuator’s link and its successive time derivatives are

\[
\begin{align*}
\epsilon_p &= q^{des} - x_1 \\
\dot{\epsilon}_p &= \dot{q}^{des} - x_2 \\
\ddot{\epsilon}_p &= \ddot{q}^{des} - \frac{\nu}{J} x_3 + d_2 \\
\dddot{\epsilon}_p &= \dddot{q}^{des} - \frac{\nu}{J} x_4 + d_4
\end{align*}
\] (22)

where \(q^{des}\) is the desired trajectory of the actuator’s link, and \(\dot{q}^{des}, \ddot{q}^{des}\) and \(\dddot{q}^{des}\) are the successive time derivatives of \(q^{des}\).

Let us describe a sliding variable in terms of the trajectory error and its successive time derivatives by using

\[
\sigma_p = \dddot{\epsilon}_p + c_2 \dddot{\epsilon}_p + c_1 \dot{\epsilon}_p + c_0 \epsilon_p
\] (23)

where \(c_0, c_1, c_2\) are non-negative real numbers.³⁰ ³¹ They can be tuned by using \(c_2 = \frac{3 \sigma_{SMC}}{2}, c_1 = \frac{3 \sigma_{SMC}}{4}\) and \(c_0 = \frac{3 \sigma_{SMC}}{1}\) where \(\sigma_{SMC} \in \mathbb{R}\) represents the bandwidth of the performance controller. As \(\sigma_{SMC}\) is increased, the position control error converges to zero faster, yet the control system becomes more noise sensitive.³⁰ It should be tuned by considering the practical constraints of the system, such as the resolutions of encoders.

The derivative of Eq. (23) is

\[
\dot{\sigma}_p = -\alpha_p \tau_m + \beta_p
\] (24)

where \(\alpha_p = \frac{\nu}{J} \); and \(\beta_p = q^{des} + c_2 \dddot{q}^{des} + c_1 \dot{q}^{des} + c_0 q^{des} - \frac{\nu}{J} (c_0 x_2 + c_1 x_3 + c_2 x_4) + c_1 d_2 + c_2 \dot{d}_2 + \dot{d}_2 + \frac{\nu}{J} d_4\).

The robust position control signal is generated as follows:

\[
\tau_m = \alpha_p^{-1} \rho_p \text{sgn} (\sigma_p) + \beta_p
\] (25)

where \(\rho_p > 0\) is the discontinuous control gain of SMC, \(\text{sgn} ()\) is the signum function and

\[
\begin{align*}
\dot{\beta}_p &= q^{des} + c_2 \dddot{q}^{des} + c_1 \dddot{q}^{des} + c_0 \dddot{q}^{des} - \frac{\nu}{J} (c_0 x_2 + c_1 x_3 + c_2 x_4) + \\
&+ c_1 \dot{d}_2 + c_2 \dot{d}_2 + \dot{d}_2 + \frac{\nu}{J} d_4
\end{align*}
\] (26)

where \(\dot{d}_2, \ddot{d}_2, \dot{\dot{d}}_2\) and \(\dot{d}_4\) are the estimations of \(d_2, \dot{d}_2, \ddot{d}_2\) and \(d_4\), respectively.

4.2. Robust force controller synthesis

Eq. (8) can be rewritten by using

\[
\begin{align*}
\dot{x}_1 &= x_2 \\
\dot{x}_2 &= \frac{1}{J} \tau_m - d
\end{align*}
\] (27)

where \(x_1 = \theta\); \(x_2 = \dot{\theta}\); and \(d = \frac{\nu}{J} x_2 + \frac{\nu}{J} \) is the matched disturbance in force/impedance control.
A sliding mode motion controller synthesis for SEAs

Fig. 2. Block diagram of the robust motion controller. ∗ is P in position control and F in force control. \( \chi^{des} \) represents reference trajectories, i.e., it is \([q^{des}, \dot{q}^{des}, \ddot{q}^{des}, \ldots, q^{\ldots des} - \chi]\) in position control and \([\theta^{des}, \dot{\theta}^{des}, \ddot{\theta}^{des}]\) in force control.

The trajectory tracking error of the SEA's motor, that is, the trajectory tracking error of the actuator’s spring force/torque, and its derivative are

\[
e_F = \theta^{des} - x_1
\]

\[
\dot{e}_F = \dot{\theta}^{des} - x_2
\]

where \( \theta^{des} \) is given in Eq. (5), and \( \dot{\theta}^{des} \) is the derivative of \( \theta^{des} \).

Let us define a sliding variable in terms of the trajectory error and its time derivative by using Eq. (28).

\[
\sigma_F = \dot{e}_F + c_{0_F} e_F
\]

where \( c_{0_F} \) is a non-negative real number. The convergence rate of the force control error can be similarly adjusted by tuning \( c_{0_F} \), for example, as \( c_{0_F} \) is increased the force control error goes to zero faster yet the noise-sensitivity deteriorates.

The derivative of Eq. (29) is

\[
\dot{\sigma}_F = -\alpha_F \tau_m + \beta_F
\]

where \( \alpha_F = 1/J_n \) and \( \beta_F = \ddot{\theta}^{des} + c_{0_F} \dot{\theta}^{des} - c_{0_F} x_2 + d \).

The robust force control signal is generated as follows:

\[
\tau_m = \alpha_F^{-1} \rho_F \text{sgn} (\sigma_F) + \alpha_F^{-1} \hat{\beta}_F
\]

where \( \rho_F > 0 \) is the discontinuous control gain of SMC, and

\[
\hat{\beta}_F = \ddot{\theta}^{des} + c_{0_F} \dot{\theta}^{des} - c_{0_F} x_2 + \hat{d}
\]

where \( \hat{d} \) is the estimation of \( d \).

It is noted that Eq. (31) requires the acceleration measurement of the SEA's link. The control signal can be generated without acceleration measurement by using

\[
\hat{\beta}_F = c_{0_F} \dot{\theta}^{des} - c_{0_F} x_2 + \hat{d}
\]

The block diagram of the proposed motion controller is illustrated in Fig. 2.

4.3. Stability analysis of the robust motion controllers

Let us consider the following Lyapunov function candidate:

\[
V = \frac{1}{2} \sigma_\ast^2
\]

where ∗ is P in position control and F in force control.
The derivative of Eq. (34) is

$$\dot{V} = \sigma_a \left( -\rho_a \text{sgn} (\sigma_a) - (\beta_a - \hat{\beta}_a) \right)$$  \hspace{1cm} (35)$$

$$\dot{V} \leq -\left( \rho_a - \left| \beta_a - \hat{\beta}_a \right| \right) |\sigma_a|$$  \hspace{1cm} (36)$

Since disturbance estimation error is bounded when the observer is properly tuned, $\beta_a$ is also bounded. It can be expressed as follows:

$$\left| \beta_p - \hat{\beta}_p \right| \leq c_{1p} \left| \ddot{d}_2 - \hat{\ddot{d}}_2 \right| + c_{2p} \left| \dot{d}_2 - \hat{\dot{d}}_2 \right| + \frac{\kappa}{\sqrt{T}} \left| d_4 - \hat{d}_4 \right| \leq \delta_{\beta_p}$$  \hspace{1cm} (37)$

where $\delta_{\beta_p} > 0$ and $\delta_{\beta_F} > 0$ are real numbers.

If SMC gain is $\rho_a = \delta_{\beta_a} + \mu \sqrt{2}$ where $\mu > 0$, then $\sigma_a(t)$ converges to zero in a finite time, that is,

$$T \leq \frac{\sqrt{2}}{\mu} |\sigma_a(t_0)|$$  \hspace{1cm} (38)$

where $T$ is the maximum convergence time, and $t_0$ is the arbitrary initial time. Hence, the trajectory tracking errors given in Eqs. (22) and (28) exponentially go to zero.30,31

Compared to the robust position control problem of an SEA, its robust force control problem suffers from only the matched disturbances. Although the matched disturbances can be directly suppressed by using conventional SMC, the force controller may suffer from chattering due to high SMC gain in practice. In the proposed robust motion controllers, DOB not only improves the robustness against disturbances but also suppresses the chattering by allowing to lower the discontinuous SMC gain constraint.

4.4. Continuous robust motion controller synthesis

4.4.1. Quasi-SMC. Continuous control signal can be obtained by using the approximation of the signum function as follows:

$$\text{sgn} (\sigma_a) \approx \frac{\sigma_a}{|\sigma_a| + \varepsilon}$$  \hspace{1cm} (39)$

where $\varepsilon \neq 0 \in \mathbb{R}$.

There is a trade-off between the control signal chattering and the robustness against disturbances in Quasi-SMC. As $\varepsilon$ is increased, the fluctuation of the control signal is suppressed yet the robustness deteriorates. However, as $\varepsilon$ is decreased, the robustness improves yet the fluctuation of the control signal is increased.

4.4.2. Continuous SMC. Without degrading the robustness of the proposed motion controllers, continuous control signal can be obtained by using continuous SMC.

Let us design new sliding variables by using

$$\tilde{\sigma}_p = \tilde{\sigma}_p + \tilde{c}_{3p} \ddot{e}_p + \tilde{c}_{2p} \dot{e}_p + \tilde{c}_{1p} e_p + \tilde{c}_0 e_F$$  \hspace{1cm} (40)$

$$\tilde{\sigma}_F = \tilde{\sigma}_F + \tilde{c}_{1F} e_F + \tilde{c}_0 e_F$$

where $\tilde{c}_0, \tilde{c}_{1p}, \tilde{c}_{2p}, \tilde{c}_{3p}, \tilde{c}_0$, and $\tilde{c}_{1F}$ are positive real numbers, and they can be similarly tuned to adjust the convergence rates of the position and force control errors.

Continuous control signal, which forces sliding variables ($\tilde{\sigma}_p$ and $\tilde{\sigma}_F$) to converge zero in a finite time, is designed as follows:31

$$\tau_m = \int \alpha_a^{-1} \rho_a \text{sgn} (\tilde{\sigma}_a) \, dt + \alpha_a^{-1} \dot{\beta}_a$$  \hspace{1cm} (41)$

where * is $P$ in position control and $F$ in force control.
A sliding mode motion controller synthesis for SEAs

Table I. Nominal model parameters of SEA.

| Parameters | Description                  | Values          |
|------------|------------------------------|-----------------|
| $J_n^m$    | Inertia of motor             | $2.2 \times 10^{-6}$ kg m$^2$ |
| $J_l^n$    | Inertia of link              | $4 \times 10^{-6}$ kg m$^2$   |
| $k^n$      | Torsional spring stiffness   | 0.14 Nm/rad     |

Fig. 3. A prototype of the novel SEA.

Continuous control signal is obtained by integrating the signum function in Eq. (41). The main drawback of continuous SMC is that the acceleration measurement is required in the design of the sliding variables in Eq. (40).

5. Experiments

This section verifies the proposed robust motion controller with the experimental results of a novel SEA illustrated in Fig. 3. The novel SEA has a two-state variable-stiffness actuation mechanism which consists of serially connected a hard torsional spring and a soft linear spring. The position and force control experiments were conducted by neglecting the linear spring of the novel SEA; that is, a conventional SEA structure with a torsional spring was used in the experiments. The nominal parameters of the SEA’s dynamic model are given in Table I. To implement the sliding mode motion controllers, a dSPACE real-time control system was used by setting its sampling frequency at 2 KHz. The resolutions of the motor (Maxon EC-4pole) and link encoders were 2048 PPR and 1024 PPR, respectively.

Let us begin by presenting position control experiments with discontinuous SMC method. Figure 4(a) illustrates a trajectory tracking experiment when conventional sliding mode controller is implemented; that is, the mismatched disturbances are neglected in the sliding mode controller synthesis. A constant weight was attached to the link of the actuator that did not interact with environment. To improve the robustness, the discontinuous control gain was gradually increased between 9 and 14 s. It is clear from the figure that the SEA’s link cannot track the reference sine wave by using a conventional sliding mode controller due to disturbances. As the discontinuous control gain was increased, the link of the actuator started to follow the sinusoidal reference input. However, the performance of the trajectory tracking control was very poor, and the chattering of the control signal was very high. It is illustrated between 9 and 19 s in this figure. Figure 4(b) illustrates a trajectory tracking experiment when the proposed sliding mode controller is implemented, that is, the sliding surface is designed by using the estimations of the disturbances. The same weight was attached to the link of the actuator, and it was disturbed with random external disturbances between 10 and 15 s as shown in the figure (see the estimations of the matched and mismatched disturbances). This figure shows that the link of the SEA can track the sine wave with high accuracy when the disturbances are suppressed by using the proposed sliding mode controller. A regulation control experiment is illustrated in Fig. 4(c). Similarly, the link of the SEA was disturbed with random external disturbances between 13 and 19 s (see the estimations of the matched and mismatched disturbances). As shown in the figure, the proposed controller can precisely suppresses disturbances, and the actuator’s link can track step input with high accuracy. The performance of disturbance suppression can be improved...

(b) Trajectory tracking control experiment via the proposed sliding mode position controller. Reference is a sine wave with 0.1592 rad amplitude and 1 Hz frequency.

(c) Regulation control experiment via the proposed sliding mode position controller. Reference is a step input with 0.1592 rad magnitude.

Fig. 4. Position control experiments when discontinuous-SMC-based controllers are implemented. The transient response of the SEA’s link suffered from vibration as the resonance modes of the compliant actuator were neglected in the sliding mode controller synthesis. The vibration of the SEA’s link can be suppressed by either using a continuous trajectory as shown in Fig. 4(b) or damping the resonance modes of the compliant actuator as proposed in ref. [7]. Figures 4(b) and 4(c) show that the discontinuous-SMC-based robust position control.
controller does not suffer from high control signal chattering since lower SMC gains can be used by cancelling disturbances via DOB.

Let us now present position control experiments by using Quasi-SMC and continuous SMC methods. All the experiments were conducted by using the proposed sliding mode controller which treated the mismatched disturbances in the controller synthesis. The link of the SEA was similarly disturbed.
with random external disturbances between 7 and 14 s as shown in Fig. 5. Figures 5(a) and 5(b) illustrate trajectory tracking experiments when Quasi-SMC is implemented with different approximations of the signum function. As $\varepsilon$ was increased, the sliding mode controller became more sensitive to disturbances, and the accuracy of the link trajectory deteriorated. The control signal fluctuations were similar when different $\varepsilon$ values were used in Quasi-SMC because low discontinuous control gains were applied by cancelling disturbances via DOB in the proposed sliding mode position controller. Figure 5(c) illustrates trajectory tracking experiment when continuous SMC is implemented. The position control performance of the continuous-SMC-based robust controller was better than that of the Quasi-SMC-based robust controller. The link of the SEA tracked the sine wave with high accuracy. However, the continuous-SMC-based robust controller suffered from noise because acceleration estimation, which was obtained by differentiating position measurement twice, was used in the controller synthesis.

Figures 4(b) and 5 show that control signal chattering is not a severe problem in the proposed sliding mode controller. Since similar tracking performance can be achieved with practical control signal, authors recommend the proposed discontinuous SMC method for SEAs.

Last, let us present force/impedance control experiments with discontinuous SMC method. Two different robust force/impedance control experiments were performed to validate the proposed sliding mode force controller. In the first experiment, force trajectory tracking and regulation control experiments were performed by contacting with a passive stiff environment (metal). In the second experiment, a physical human–robot interaction experiment was performed when zero-force control was implemented. Figure 6(a) illustrates a force/impedance trajectory tracking experiment when the SEA’s link initially contacts with the stiff environment. It is clear from the figure that the trajectory of the spring force is tracked with high accuracy by suppressing the matched disturbances. Since the matched disturbances were cancelled by using DOB in the inner-loop, the robustness of the force control system was achieved without suffering from control signal chattering. Figure 6(b) illustrates a force/impedance regulation experiment when the SEA’s link does not initially contact with the stiff environment. Since the approaching speed of the SEA’s link was neglected in this experiment, a high overshoot (impact force) was observed in the beginning of the contact motion. To eliminate or lower the overshoot in force control, one should treat approaching speed of the actuator’s link. The figure shows that the regulation experiment can be conducted with high accuracy by using the proposed sliding mode force controller. Compared to the position regulation experiment, the performance of the force regulation experiment did not suffer from vibration. However, the resonance modes influenced the system as a disturbance. The control signal was automatically adjusted so that the disturbance, that is, the vibration, was precisely suppressed. The results of the physical human–robot interaction experiment are illustrated in Fig. 6(c). The force control experiment was performed by pushing/pulling the SEA’s link and applying zero-force reference input. As it is shown in the figure, the SEA can physically interact with a human being in a safe and sound manner when the proposed sliding mode force controller is implemented.

6. Conclusion

This paper has proposed a robust motion controller for SEAs by using DOB and SMC. All disturbances are lumped into fictitious disturbance variables so that practical dynamic models are derived for position and force control applications. It is shown that the force control dynamics is of second order and suffers from matched disturbances; however, the position control dynamics is of fourth order and suffers from mismatched disturbances as well as matched disturbances. Therefore, an SEA’s position control problem is more complicated than its force control problem. By combining DOB and SMC, not only the disturbances of an SEA are eliminated but also the discontinuous control signal chattering is significantly suppressed. When the proposed sliding mode controllers are implemented, (1) the position and force trajectories of an SEA can be tracked with high accuracy and (2) an SEA can physically interact with active and passive environments in a safe and sound manner. Position and force control experiments are presented to validate the robust motion controllers.
