Abstract

The strangeness-changing (ΔS = 1) weak baryon-baryon interaction is studied through the nonmesonic weak decay of double-Λ hypernuclei. Besides the usual nucleon-induced decay ΛN → NN we discuss novel hyperon-induced decay modes ΛΛ → ΛN and ΛΛ → ΣN. These reactions provide unique access to the exotic ΛΛK and ΛΣK vertices which place new constraints on Chiral Perturbation Theory (χPT) in the weak SU(3) sector. Within a meson-exchange framework, we use the pseudoscalar π, η, K octet for the long-range part while parametrizing the short-range part through the vector mesons ρ, ω, K*. Realistic baryon-baryon forces for the S = 0, −1 and −2 sectors account for the strong interaction in the initial and final states. For $^6_{\Lambda\Lambda}$He the new hyperon-induced decay modes account for up to 4% of the total nonmesonic decay rate. Predictions are made for all possible nonmesonic decay modes.

I. INTRODUCTION

The production and weak decay properties of strangeness-rich systems is of fundamental importance for our understanding of relativistic heavy-ion collisions and certain astrophysical phenomena, such as neutron stars. The simplest systems with strangeness, hypernuclei with one or two bound Λ’s, have been used to study both the strong and the weak baryon-baryon (BB) interaction in the SU(3) sector. Until now, hypernuclear weak decay represents the only source of information on the |ΔS| = 1 four fermion interaction where, in contrast to the weak ΔS = 0 NN case, both the weak parity-conserving (PC) and parity-violating (PV) amplitudes can be studied.

In the absence of exact solutions to low-energy QCD, effective field-theory techniques based on chiral expansions have been fairly successful in the description of hadronic observables in the (non-strange) SU(2) sector. The stability of the chiral expansion is less clear for the SU(3) sector, due to the significant amount of SU(3) symmetry breaking. A well-known failure of SU(3) chiral perturbation theory has been the prediction [1] of the four
PC $P$-wave amplitudes in the weak nonleptonic decays of octet baryons, $Y \to N\pi$, with $Y = \Lambda, \Sigma$ or $\Xi$. Since large cancellations among tree-level amplitudes are held responsible for the problem with the weak $P$-wave octet amplitudes, it is imperative to assess whether this situation is universal within SU(3) $\chi$PT or limited to a few exceptional cases. However, other weak octet baryon-baryon-meson (BBM) vertices can only be accessed through reactions that allow for the virtual exchange of mesons, such as the reactions $\Lambda N \to NN$ and $\Lambda\Lambda \to \Lambda(\Sigma)N$. The process $\Lambda N \to NN$ has been extensively studied in an approach where the long-range part of this interaction is based on the exchange of the SU(3) pseudoscalar meson octet ($\pi$, $K$, and $\eta$). The pseudoscalar baryon-baryon-meson vertices are considered fixed by experiment in the case of the pion, and by SU(3) chiral algebra for the $K$ and the $\eta$. Since the large momentum transfer in the reaction (typically 400 MeV/c) leads to a mechanism where short-range effects must be included, they have been modelled either through the exchange of the vector meson octet ($\rho, \omega$ and $K^*$) or quark exchange. The vector baryon-baryon-meson vertices are constrained by much weaker SU(6) considerations.

Since the late 1960’s, the production and decay of single-$\Lambda$ hypernuclei has been studied experimentally in great detail, but only very few events involving doubly-strange objects have been reported. Double $\Lambda$ hypernuclei are produced via the $(K^-, K^+)$ reaction at KEK (Japan) and BNL (USA), where a $\Lambda\Lambda$ hypernuclear fragment can be formed by $\Xi^-$ capture on a nucleus. The FINUDA experiment at DAΦNE (Frascati, Italy) can produce double-$\Lambda$ hypernuclei by stopping slow $K^-$ (coming from the $\Phi$ decay) into thin targets to obtain data with higher energy resolution. Studying the weak decay of those objects opens the door to a number of new exotic $\Lambda$-induced decay modes: $\Lambda\Lambda \to \Lambda n$ and $\Lambda\Lambda \to \Sigma N$. Both of these decays would involve hyperons in the final state and should be distinguishable from the ordinary $\Lambda N \to NN$ mode. The $\Lambda\Lambda \to \Lambda n$ channel is especially intriguing since the dominant pion exchange is forbidden, thus forcing this reaction to occur mostly through kaon exchange. One would therefore gain access to the weak $\Lambda\Lambda K$ and $\Lambda\Sigma K$ vertices.

In this paper, we extend previous weak decay calculations of single-$\Lambda$ hypernuclei into the $S=\Omega=2$ sector, thus exploring the power of the $\Lambda\Lambda \to \Lambda(\Sigma)N$ process to shed light on the novel weak vertices. In order to take into account the effects of the strong interaction between the baryons, correlated wave functions are obtained from a $G$-matrix calculation for the initial $\Lambda N$ and $\Lambda\Lambda$ states, while a $T$-matrix equation is solved for the final NN and YN states using the Nijmegen interaction models, in particular the NSC97f one.

II. DECAY RATE

In the weak nonmesonic decay of double-$\Lambda$ hypernuclei, new hyperon-induced mechanisms, the $\Lambda\Lambda \to \Lambda N$ and the $\Lambda\Lambda \to \Sigma N$ transitions (denoted as $\Lambda\Lambda \toYN$ throughout the text) become possible in addition to the dominant $\Lambda N \to NN$ decay mode. Assuming
the initial hypernucleus to be at rest, the NMD rate is given by:

\[
\Gamma_{nm} = \int \frac{d^3k_1}{(2\pi)^3} \int \frac{d^3k_2}{(2\pi)^3} \times \sum_{M_I(R)} \frac{1}{2J+1} \frac{\delta(M_H - E_R - E_1 - E_2)}{(2\pi)^3} |M_{i\rightarrow f}|^2 ,
\]

where the quantities \(M_H, E_R, E_1\) and \(E_2\) are the mass of the hypernucleus, the energy of the residual \((A-2)\)-particle system, and the total asymptotic energies of the emitted baryons, respectively. The integration variables \(\vec{k}_1\) and \(\vec{k}_2\) stand for the momenta of the two baryons in the final state. In the expression above, the momentum-conserving delta function has been used to integrate over the momentum of the residual nucleus. The sum, together with the factor \(1/(2J+1)\), indicates an average over the initial hypernucleus spin projections, \(M_I\), and a sum over all quantum numbers of the residual \((A-2)\)-particle system, \(\{R\}\), as well as the spin and isospin projections of the emitted particles, \(\{1\}\) and \(\{2\}\). The total nonmesonic decay rate can be written as:

\[
\Gamma_{nm} = \Gamma_{NN} + \Gamma_{YN} ,
\]

where the rate corresponding to \(\Lambda N \rightarrow NN\) transitions

\[
\Gamma_{NN} = \Gamma_n + \Gamma_p ,
\]

is divided into a neutron-induced rate, \(\Gamma_n : \Lambda n \rightarrow nn\) and a proton-induced one, \(\Gamma_p : \Lambda p \rightarrow np\), while the \(\Lambda\)-induced transitions \(\Lambda \Lambda \rightarrow YN\) give rise to \(\Lambda n, \Sigma^0 n\) and \(\Sigma^- p\) final states, hence:

\[
\Gamma_{YN} = \Gamma_{\Lambda n} + \Gamma_{\Sigma^0 n} + \Gamma_{\Sigma^- p} .
\]

Note that while the individual rates have been written above as exclusive observables, in principle, charge-exchange final state interactions (FSI) with the residual nucleus obscurs a clean experimental discrimination of these channels on the basis of the charge of the emitted particles. Monte Carlo intranuclear cascade models are necessary \[12\] to extract the partial weak decay rates of hypernuclei from experiment \[13\]. The impossibility of measuring the partial rates directly from the charge of the emitted particles was also shown in the case of the weak decay of the hypertriton \[14\], a system where the strong interaction effects can be treated exactly using Fadeev equations with a realistic baryon-baryon potential.

In order to draw conclusions regarding the weak dynamics, one has to write the hypernuclear transition amplitude, \(M_{i\rightarrow f}\), in terms of the elementary two-body transitions, \(B_1B_2 \rightarrow B_3B_4\), and nuclear structure details have to be treated with as few approximations and ambiguities as possible. We work in a shell-model framework, hence the \(\Lambda\) hyperons and the nucleons are described by single-particle orbitals. In addition, we assume a weak coupling scheme by virtue of which the \(\Lambda\) hyperons couple only to the ground state of the nuclear core. Therefore, in the case of the \(^6\Lambda\Lambda\)He hypernucleus studied here, with quantum numbers \(J_I = M_I = 0, T_I = M_{T_I} = 0\), the state will be given by
energies of the three observed double Λ-hypernuclei, the nucleon parameter is chosen to account for the relative distance obtained in Ref. [15] by adjusting their model parameters to the binding energies of the three observed double Λ-hypernuclei, $^6_{\Lambda\Lambda}$He, $^{10}_{\Lambda\Lambda}$B and $^{13}_{\Lambda\Lambda}$B [1] [3].

To obtain the rate corresponding to the $\Lambda N \rightarrow NN$ transition, with the initial $N$ being $n(t_N = -1/2)$ or $p(t_N = 1/2)$, we have to write the non-strange nuclear core as one nucleon coupled to a 3-particle system (with quantum numbers $J_3, M_3, T_3$ and $M_{T_3}$) and decouple one of the two $\Lambda$’s in the cluster. Therefore, the initial $\Lambda N$ pair will convert into a final NN pair with quantum numbers $\vec{k}_1 s_1 t_1, \vec{k}_2 s_2 t_2$, leaving a residual 4-particle system with quantum numbers $J_R, M_R, T_R, M_{T_R}$. Performing all the necessary decoupling and recoupling operations, we finally arrive at:

$$
\mathcal{M}_{\Lambda N \rightarrow NN} = \langle \vec{k}_1 s_1 t_1, \vec{k}_2 s_2 t_2; \lambda; A T_R M_{T_R} \rangle \hat{O} \langle \vec{k}_1 \vec{k}_2 \rangle \langle \Lambda \Lambda \rangle \langle 0 | \Lambda \rangle \\
= \sum_S \sum_T \sum_{m_N} \sum_{S_0} \langle TM_T | \frac{1}{2} t_1, \frac{1}{2} t_2 \rangle \langle TM_T | \frac{1}{2} t_1, \frac{1}{2} t_N \rangle \\
\times \langle T_3 M_{T_3} | \frac{1}{2} t_N | T_c = 0 M_c = 0 \rangle \langle J_3 M_3, \frac{1}{2} m_N | J_c = 0 M_c = 0 \rangle \\
\times \langle \frac{1}{2} (m_N - M_{S_0}), J_3 M_3 | J_R M_R \rangle \langle SM_S | \frac{1}{2} s_1, \frac{1}{2} s_2 \rangle \\
\times \langle \frac{1}{2} (M_{S_0} - m_N), \frac{1}{2} (m_N - M_{S_0}) | J_A = 0 M_A = 0 \rangle \\
\times \langle \frac{1}{2} (M_{S_0} - m_N), \frac{1}{2} m_N | S_0 M_{S_0} \rangle \\
\times \langle \hat{K} | \Psi_{\Lambda NN}^{CM} \rangle \langle \vec{k}, SM_S, TM_T | \hat{O} | \Psi_{\Lambda NN}^{rel} \rangle \langle S_0 M_{S_0}, TM_T \rangle ,
$$

where $T_3 = 1/2, M_{T_3} = -t_N, J_3 = 1/2, M_3 = -m_N, M_{T_R} = -t_N, M_{S_0} = -M_R, M_S = s_1 + s_2$ and $M_T = t_N - 1/2 = t_1 + t_2$. We have assumed the $\Lambda$ at the weak vertex to behave as a $|\frac{1}{2} - \frac{1}{2} \rangle$ isospinor in order to naturally incorporate the experimentally observed $\Delta I = 1/2$ rule. The momentum states $\vec{k}_1$ and $\vec{k}_2$ have been transformed to total $(\vec{k} = \vec{k}_1 + \vec{k}_2)$ and relative $(\vec{k} = (\vec{k}_1 - \vec{k}_2)/2)$ momenta and the final two-nucleon state, $(\vec{k}, SM_S, TM_T)$, must be properly antisymmetrized, which means that the factor $(1 - (-1)^{L+S+T})/\sqrt{2}$ will appear when a decomposition in partial waves is performed for the outgoing plane wave.

For the $\Lambda\Lambda \rightarrow YN$ transition we don’t need to decouple one of the hyperons from the cluster, neither a nucleon from the core. The residual 4-particle system, which coincides with the $^4$He core in Eq. (4), contains no strangeness, while the final two-particle state contains one hyperon that can be either a $\Lambda$ ($|Y t_Y \rangle = |00\rangle$), a $\Sigma^{-}$ ($|Y t_Y \rangle = |1-1\rangle$) or a $\Sigma^0$ ($|Y t_Y \rangle = |10\rangle$). The $\Lambda\Lambda \rightarrow YN$ hypernuclear amplitude is given by:
\[ M_{\Lambda \Lambda \rightarrow Y N} = \langle \vec{k}_N s_N t_N, \vec{k}_Y s_Y t_Y; \, ^4\text{He} \mid \hat{O} \mid ^6\text{He} \rangle \frac{1}{2} - \frac{1}{2} \rangle \Lambda \]

\[ = \sum_{S,M_S} \frac{1}{2} s_N \frac{1}{2} s_Y |SM\rangle \langle \frac{1}{2} t_N, Y t_Y |TM\rangle \]

\[ \times \langle \vec{k} | \Psi_{\Lambda \Lambda}^\text{CM} \rangle \langle \vec{k}, SM, TM \mid \hat{O} \mid \Psi_{\Lambda \Lambda}^\text{rel}, S_0 M_{S_0}, T M_{T_0} \rangle , \quad (7) \]

where \( S_0 = M_{S_0} = 0, T = T_0 = 1/2 \) and \( M_T = M_{T_0} = -1/2 \).

III. THE MESON EXCHANGE POTENTIAL

In a meson-exchange description, the \( \Lambda N \rightarrow NN \) and \( \Lambda \Lambda \rightarrow Y N \) transitions are assumed to proceed via the exchange of virtual mesons belonging to the ground-state pseudoscalar and vector meson octets. The amplitude, which is schematically represented by the Feynman diagram depicted in Fig. [1], reads

\[ M_{\Lambda N} = \int d^4x \, d^4y \, \vec{\Psi}_{p_3}(x) \Gamma_1 \Psi_{p_1}(x) \Delta_{M}(x - y) \, \vec{\Psi}_{p_4}(y) \Gamma_2 \Psi_{p_2}(y) , \quad (8) \]

where \( \Psi_{p}(x) = e^{-ipx}u(p) \) is the free baryon field of positive energy, \( \Gamma_i \) the Dirac operator characteristic of the baryon-baryon-meson (BBM) vertex and \( \Delta_{M}(x - y) \) the meson propagator.

In Table [I] we show the strong and weak hamiltonians for pseudoscalar (PS) and vector (V) mesons. The constants \( A, B, \alpha, \beta \) and \( \epsilon \) correspond to the weak couplings, while \( g \) \((g^V, g^T)\) represents the strong (vector, tensor) one.

The nonrelativistic reduction of this amplitude gives us the potential in momentum space [3], which for pseudoscalar mesons reads:

\[ V_{ps}(q) = -G_F m_{\pi}^2 g \frac{2}{2M_1} \left( \hat{A} + \frac{\hat{B}}{2M_1} \vec{\sigma}_1 \vec{q} \right) \frac{\vec{q}_2 \vec{q}}{q^2 + \mu^2} , \quad (9) \]

where \( G_F m_{\pi}^2 = 2.21 \times 10^{-7} \) is the Fermi weak constant, \( \vec{q} \) is the momentum carried by the meson directed towards the strong vertex, \( \mu \) the meson mass and \( M_2 (M_1) \) is the average of the baryon masses at the strong (weak) vertex. For vector mesons the potential reads:

\[ V_{v}(q) = G_F m_{\pi}^2 \left( g^V \hat{\alpha} - \frac{(\hat{\alpha} + \hat{\beta})(g^V + g^T)}{4M_1 M_2} (\vec{\sigma}_1 \times q) (\vec{\sigma}_2 \times q) - \frac{1}{2M_2} \hat{\epsilon} (g^V + g^T) (\vec{\sigma}_1 \times \vec{\sigma}_2) \vec{q} \right) \frac{1}{q^2 + \mu^2} . \quad (10) \]

In Eqs. (9), (10) the operators \( \hat{A}, \hat{B}, \hat{\alpha}, \hat{\beta} \) and \( \hat{\epsilon} \) contain, apart from the weak coupling constants, the specific isospin dependence of the potential, which is \( \vec{\sigma}_1 \vec{\sigma}_2 \) for the isovector \( \pi \) and \( \rho \) mesons, \( \vec{1} \) for the isoscalar \( \eta \) and \( \omega \) mesons and a combination of both operators for the isodoublet \( K \) and \( K^* \).

Ref. [3] introduces a compact way to write the transition potential in \( \vec{r} \)-space:
where the index $i$ runs over the different mesons exchanged ($i = 1, \ldots, 6$ represents $\pi, \eta, K, \rho, \omega, K^*$) and $\alpha$ over the different spin operators: central spin independent (C), central spin dependent (SS), tensor (T) and parity violating (PV)

$$V(\vec{r}) = \sum_i \sum_\alpha V^{(i)}_\alpha(\vec{r}) = \sum_i \sum_\alpha V^{(i)}_\alpha(r) \hat{O}_\alpha(\vec{r}) \hat{I}^{(i)}_\alpha,$$

(11)

In order to account for the finite size and structure of the particles involved in the process, form factors (FF) are included. In our previous calculations of the decay of single-\(\Lambda\) hypernuclei we used a monopole FF, $F(\vec{q}^2)$, at each vertex of the type $F(\vec{q}^2) = \exp(-\vec{q}^2/2\Lambda_i^2)$. Those cut-offs were taken from the Jülich YN interaction model \([11]\). The latest version of the Nijmegen potentials \([11]\), which is used here, also gives meson-dependent cut-offs but uses an exponential FF at each vertex of the type $F(\vec{q}^2) = \exp(-\vec{q}^2/2\Lambda_i^2)$. Therefore, the results presented here are also obtained with the exponential-type FF, although, for technical reasons, it is matched to a function of the type $\tilde{F}(\vec{q})$ at $|\vec{q}| \approx 400$ MeV/c, the most relevant momentum transfer in the weak decay transition. By construction, this type of monopole FF is equivalent to the exponential one at $|\vec{q}| = 0$ and we have verified that, up to a momentum transfer of 600 MeV/c above which the transition amplitude is negligible, the differences between both functions are less than 2%. The modified cut-offs, $\tilde{\Lambda}_i$, to be used in the monopole-type FF are listed in Table \([11]\).

To incorporate the effects of the strong baryon-baryon (BB) interaction we solve a T-matrix scattering equation in momentum space for the outgoing two-particle system (NN or YN). For the initial two-particle system ($\Lambda N$ or $\Lambda \Lambda$) we take into account medium effects, thus intermediate states only propagate into states allowed by the Pauli operator ($G$-matrix). For the initial interacting $\Lambda N$ pair we previously found \([17]\) that multiplying the independent two-particle wave function by a spin-independent correlation function of the type:

$$f(r) = \left(1 - e^{-r^2/a^2}\right)^n + b r^2 e^{-r^2/c^2},$$

(12)

with $a = 0.5$ fm, $b = 0.25$ fm$^{-2}$, $c = 1.28$ fm, $n = 2$, produced a correlated wave function which averaged the ones obtained from a microscopic finite-nucleus $G$-matrix calculation \([18]\) using the soft-core and hard-core Nijmegen models \([19]\). In the case of the interacting $\Lambda \Lambda$ system, we again assume a correlation function of the type of Eq. \([12]\). The parameters, $a = 0.80$ fm, $b = 0.12$ fm$^{-2}$, $c = 1.28$ fm and $n = 1$, are determined to reproduce the ratio between the correlated and uncorrelated $^1S_0$ $\Lambda \Lambda$ wave functions in nuclear matter at saturation density, $\Psi_{1S_0}(k, r)/j_0(kr)$, taking $k = 100$ MeV/c as a representative momentum of the two $\Lambda$’s in a finite nucleus. The nuclear-matter correlated wave function, $\Psi_{1S_0}(k, r)$, has been obtained from a coupled-channel G-matrix calculation using the NSC97f model of the new Nijmegen potentials. In Fig. \([2]\) we show the probability per unit length of...
finding two Λ particles at a distance \( r \), given by \( 4\pi r^2|\Psi_{\Lambda\Lambda}^{\text{rel}}|^2 \). The solid line corresponds to the uncorrelated two-Λ wave function, which in this work is given by the 1s harmonic oscillator wave function with the parameter \( b_{\text{rel}} = \sqrt{2}b_\Lambda \). The dashed line incorporates the calculated correlation function, \( \Psi_{1S_0}(k, r)/j_0(kr) \), a result that is well parametrized by a phenomenological correlation function of the form of Eq. (12), as shown by the dotted line.

As mentioned before, the strong BBM couplings are taken from the NSC97f [11] potential. In the weak sector only the couplings corresponding to decays involving pions are experimentally known. The weak couplings for heavy mesons are obtained following Refs. [2,20]. The PV amplitudes for the nonleptonic decays \( B \to B' + M \) involving pseudoscalar mesons are derived using the soft-meson reduction theorem and SU(3) symmetry. This allows us to relate the physical amplitudes of the nonleptonic hyperon decays into a pion plus a nucleon, \( B \to B' + \pi \), with the unphysical amplitudes involving other members of the meson and baryon octets. On the other hand, SU(6)A permits relating the amplitudes involving pseudoscalar mesons with those for vector mesons. The weak PC coupling constants are obtained using a pole model, where the pole terms due to the \( \left( \frac{1}{2} \right)^+ \) ground state (singular in the SU(3) soft meson limit) are assumed to be the dominant contribution. No meson pole terms are included. The values of these couplings for the weak vertices are listed in Table IV.

### IV. RESULTS

The results for the decay rates of \( ^6\Lambda\Lambda\text{He} \) into the different channels are summarized in Tables V, VI, and VII, where the rate is presented in units of the free Λ decay, \( \Gamma_\Lambda = 3.8 \times 10^8 \text{ s}^{-1} \). Apart from giving the various partial rates, the ratio between the neutron-induced and proton-induced decay rates, \( \Gamma_n/\Gamma_p \), is also quoted. Only \( \Delta I = 1/2 \) transitions have been considered.

We begin by discussing the results of Table V, which list calculations absent of either strong correlations (initial and final) and FF. Although the results are clearly unrealistic, they serve to illustrate, in comparison with the following table, the effect of the strong interaction on the weak decay process. The \( \Lambda N \to NN \) transitions receive contributions mainly from the \( \pi, \rho, K \) and \( K^* \) mesons; however, once short-range strong correlations are included (see Table VI), the role of the heavier mesons is strongly reduced. The results in Table V illustrate that isospin symmetry forbids isovector meson contributions, \( (\pi, \rho) \), for the uncorrelated \( \Lambda\Lambda \to \Lambda n \) decay rate and isoscalar meson contributions, \( (\eta, \omega) \), for the uncorrelated \( \Lambda\Lambda \to \Sigma N \) rates. Finally, we note that the nucleon-induced rate is about 20 times larger than the total hyperon-induced contribution.

When FF and strong correlations in the initial and final states are included, the picture changes considerably, as can be seen from the results shown in Table VI. Most of the \( \Lambda N \to NN \) rate comes from the exchange of the \( \pi \) and \( K \) mesons. Note that the small \( \Gamma_n/\Gamma_p \) ratio for the one-pion exchange mechanism substantially increases when the \( K \)-meson is incorporated due to a destructive (constructive) interference in the \( p \)-induced (\( n \)-induced) rate. This aspect is discussed recently in Ref. [4], which updates the meson-exchange model of Ref. [3] and finds agreements with results obtained by groups combining the \( \pi \) and \( K \) exchange with either a direct quark mechanism [3] or \( 2\pi \) exchange [21]. Since there are now
two Λ particles contributing to the ΛN → NN decay, one would expect the result to be roughly twice the rate in 3He, which for this potential turns out to be 0.32ΓΛ, as shown in Ref. [4]. We obtain instead a significantly larger value of ΓNN = 0.96ΓΛ. This finding can be traced to the Λ which is more strongly bound in 6ΛHe than it is in 3He by about 80% (i.e., the Λ single-particle separation energy changes from 3.12 MeV to around 5 MeV). This increased binding is reflected in the Λ single-particle wave function, with a harmonic oscillator parameter \( b_Λ = 1.6 \text{ fm} \) instead of the value \( b_Λ = 1.87 \text{ fm} \) used in the decay of single-Λ hypernuclei [3,4]. As mentioned in Sec. II, the parameter \( b_Λ = 1.6 \text{ fm} \) simulates the uncorrelated ΛΛ probability of Ref. [15], which reproduces the binding energy of the three observed double-Λ hypernuclei. There is also some influence from the slightly different kinematics involved in the ΛN → NN decay of 6ΛHe with respect to that in 3He.

From the results presented in Table VI, we observe that the ΛΛ → Λn rate receives a tiny contribution from the isovector π and ρ mesons. This is due to the combined transition ΛΛ \( ^{\text{weak}} \rightarrow \Sigma N \) \( ^{\text{strong}} \rightarrow \Lambda N \), which is possible through the coupling between ΛN and ΣN states induced by the strong interaction. Analogously, the strong ΛN – ΣN coupling also induces very small contributions from the isoscalar mesons to the ΣN rate, \( \Gamma_{\Sigma N} \).

We find the rate \( \Gamma_{\Lambda n} \) to be dominated by \( K \)-exchange. We note that the \( \pi + K \) contribution is very similar to the value for \( K \)-exchange alone; adding the \( \eta \) meson decreases the rate by 35%. However, there is strong evidence that we are overestimating the role of the \( \eta \) meson by using strong \( \eta NN \) and \( \eta \Lambda \Lambda \) couplings that rely on SU(3) symmetry. All indications from a careful analysis of reactions like \( \eta \) photoproduction point towards a \( \eta NN \) coupling much smaller than the one provided by SU(3) symmetry. In this case, the weak decay of double-Λ hypernuclei going to final Λn states would be almost solely determined by \( K \) exchange and the measurement of this decay channel would provide valuable information on the weak ΛΛK couplings. In particular, since this partial rate is dominated by PC transitions, as can be inferred from the values of the ΛΛK \( ^{0} \) weak couplings listed in Table [V] one would gain access to the PC ΛΛK \( ^{0} \) amplitude. The rate to final ΣN states, \( \Gamma_{\Sigma N} \), on the other hand is very small and, as expected, dominated by the \( \pi \)-exchange mechanism.

The ratios between the rates that include correlations are:

\[
\frac{\Gamma_{\Sigma N}}{\Gamma_{\Sigma N}} : \frac{\Gamma_{\Lambda N}}{\Gamma_{\Sigma N}} : \frac{\Gamma_{\Sigma N}}{\Gamma_{\Sigma N}} \approx 320 : 12 : 1 \nonumber .
\]

Correlations have a stronger influence on the YN channels, which are a factor 30 – 300 smaller compared to the NN rate, even though the ΣN transition allows a final state with a lower relative momentum and, therefore, is less sensitive to the strongly repulsive core of the YN interaction. However, the NN rate is dominated by tensor transitions that are absent in the YN channels because the interacting ΛΛ pair is in a \( ^{1}S_0 \) state. With the tensor strength distributed towards larger distances compared to those for central and parity-violating transitions, the NN transition becomes comparatively less affected by strong correlations than the YN ones. Note that correlations tend to increase the ΛN rate while decreasing the ΣN rate. The reason is that the uncorrelated ΣN rate is dominated by \( \pi \) and \( K^* \) exchanges, the \( K^* \) contribution being about twice that of the \( \pi \) meson, whereas the ΛN rate comes mainly from strange meson exchange, with the \( K \) contribution twice as large as that of the \( K^* \). Therefore, the suppression of short-range physics induced by correlations affects the ΣN rate more than the ΛN one. In addition, it is known [23,24] that the ΣN interaction for the
new Nijmegen potentials is quite repulsive in the $I = 1/2$ channel, affecting the $\Sigma N$ wave functions significantly, which are pushed out from the weak potential interaction range.

The results for various approaches to the treatment of FSI are compared in Table VII. Those labelled with “FSI eff.” have been obtained by multiplying the free NN, $\Lambda N$ and $\Sigma N$ final states by the momentum and channel independent function $1 - j_0(q_c r)$, with $q_c = 3.93$ fm$^{-1}$. As recently discussed in Ref. [4], treating FSI in this simplified phenomenological fashion overestimates the rate $\Gamma_{NN}$ calculated rigorously with a $T$-matrix by about a factor of two. The rate $\Gamma_{\Lambda n}$ obtained with the phenomenological FSI treatment is almost one order of magnitude smaller compared with the result obtained within a $T$-matrix approach, while on the other hand, the rate $\Gamma_{\Sigma N}$ is overpredicted by almost an order of magnitude. As in Ref. [4], we again find that in order to be able to extract information on the weak decay amplitudes a careful treatment of FSI is essential in the study of the weak decay of double-$\Lambda$ hypernuclei.

We finally compare our results with the ones presented recently by Itonaga et al. [25], where the weak decay mechanism contains $\pi$, $\rho$ and correlated two-pion exchange with scalar ($\sigma$) and vector ($\rho$) quantum numbers. The $\Lambda$ wave function in $^6\Lambda\Lambda$He was taken the same as in their $^5\Lambda$He calculation [29], thus neglecting the possible effect of a stronger binding of the $\Lambda$ in a double-$\Lambda$ hypernucleus. Hence, the nucleon-induced rate obtained in [25] is $\Gamma_{NN} = 0.753\Gamma_{\Lambda}$, equal to twice their decay rate in $^5\Lambda$He. This rate is about 20% smaller than the one obtained here. The rates for $\Lambda n$ and $\Sigma N$ final states, $\Gamma_{\Lambda n} = 0.025\Gamma_{\Lambda}$ and $\Gamma_{\Sigma N} = 0.0012\Gamma_{\Lambda}$, are about a factor two smaller than the ones obtained in this work. We note that the $\Lambda\Delta$ correlation function used in Ref. [25] is in fact the $^1S_0$ $\Lambda N$ one used in their study of the decay of $^5\Lambda$He. We also note that the $K$-exchange mechanism, dominant in the $\Lambda\Lambda \rightarrow \Lambda n$ transition amplitude, is absent in the work of Ref. [25].

In Ref. [3], we explored SU(3) symmetry breaking effects in the decay of single-$\Lambda$ hypernuclei by using weak NNK couplings derived in the framework of heavy baryon chiral perturbation theory [27], where one-loop SU(3) corrections to leading order were evaluated. Here we explore similar effects not only for the NNK but also for the $\Lambda\Delta K$ and $\Lambda\Sigma K$ couplings, which were calculated in Refs. [28,29]. In Table VIII we list the values for the weak PV ($S$-wave) and PC ($P$-wave) couplings involving the kaon. Compared to the ones quoted in Ref. [3], the numbers in Table VIII differ since they were obtained using a common mass splitting of 200 MeV between the octet and decuplet baryons [28,29].

Comparing the values listed in Table VIII with those in Table IV we observe that the one-loop corrected NNK $P$-wave constants are approximately a factor two smaller than the tree level ones, while the $S$-wave are very similar, except for the $pnK^+$ coupling, which, again, is half the tree-level value. This explains the reduced $K$-exchange contribution to the nucleon-induced rates with respect to the tree-level result. Note that the magnitude of the (constructive) interference between $\pi$ and $K$ in the $nn$ channel has not changed much, while it has become less destructive in the $np$ channel, thereby producing a smaller $\Gamma_n/\Gamma_p$ ratio. Once all the mesons are included, the NN rate obtained with the one-loop corrected NNK couplings is a factor 1.4 larger than that obtained with the tree-level values, while the ratio $\Gamma_n/\Gamma_p$ is smaller by a factor of two.

Although the one-loop corrected $\Lambda\Delta K$ couplings of Table VIII are not much different from the corresponding tree-level values, they lead to a reduction of the $K$-meson exchange contribution to the $\Lambda n$ rate by about a factor two. Hence, the contribution of the $\eta$ meson
and the vector mesons becomes more relevant, making the extraction of the ΛΛK coupling from this ΛΛ → Λn decay mode more difficult.

The decay rate into final ΣN states is the only one that increases when the one-loop corrected ΛΣK couplings are used, despite the magnitude of the P-wave amplitudes being ten times smaller than the corresponding tree-level values, whereas the S-wave amplitudes are only moderately larger. In fact, Table [VI] reveals that the K-exchange contribution to the ΣN rate is two times smaller than that obtained with the tree-level ΛΣK couplings, as expected from the reduced magnitude of the couplings. However, due to the opposite sign of the loop-corrected P-wave coupling with respect to the corresponding tree level value, the interference between the π and K contributions is now constructive instead of destructive, which explains the final increased loop-corrected rate.

Finally, we have investigated how our results would change if we allowed the one-loop corrected BBK couplings to vary within their estimated error bands. The corresponding range of variation on the rates is quoted in Table [IX], where the results obtained with the tree-level BBK couplings have also been included to facilitate the comparison between both calculations. The results summarized in Table [IX] show clearly that the inclusion of weak BBK couplings obtained with one-loop corrections to the leading order in χPT produces a ΛN → NN rate 40 % larger than the tree-level value, a ratio Γn/Γp twice smaller, a ΛΛ → Λn rate roughly twice smaller, and a ΛΛ → ΣN rate almost twice as large.

V. CONCLUSIONS

In this study we investigated the nonmesonic weak decay modes of double-Λ hypernuclei within a one-meson-exchange framework. Our results are given for the specific double-Λ hypernucleus $^6\Lambda\Lambda$He, but can easily be extended to heavier systems.

The standard nucleon-induced nonmesonic ΛN → NN rate is found to be more than twice as large as in $^5\Lambda$He due to the increased binding of the second Λ hyperon. Two new hyperon-induced modes become possible, ΛΛ → Λn and ΛΛ → ΣN, the latter coming in two charge states. We find the total hyperon-induced rate to be as large as 4% of the total nonmesonic rate. This new rate is dominated by the ΛΛ → Λn mode. In fact, this transition turns out to be the more interesting one (rather than the ΛΛ → ΣN) since it allows direct access to exotic vertices like ΛΛK, unencumbered by the usually dominant pion exchange. Indeed, one-loop log corrected χPT results modify the ΛΛ → Λn by 50% while changing the ΛN → NN only at the 15% level, demonstrating the power of this weak mechanism to test χPT in the weak SU(3) sector. With a free Λ in the final state this new mode should be distinguishable from the usual nucleon-induced decay channels. Given the potential benefits to hadronic physics, the experimental program of investigating the production and decay of double-Λ hypernuclei should be intensified.

ACKNOWLEDGEMENTS

The authors would like to thank Christoph Hanhart, Barry R. Holstein, Roxanne P. Springer and Isaac Vidaña for their respective inputs and comments to different aspects of the present paper, regarding both the strong and weak baryon-baryon interaction. One of
the authors, A.P., would like to thank the Institute for Nuclear Theory and the University of Washington (Seattle, USA) where an important part of this work was developed. This work has been partially supported by the U.S. Dept. of Energy under Grant No. DE-FG03-00-ER41132, by the DGICYT (Spain) under contract PB98-1247 and by the Generalitat de Catalunya project SGR2000-24.

VI. APPENDIX

A. Weak PC couplings

In this subsection we present the expression for the PC weak coupling constants derived by using a pole model \([2]\) with only baryon poles.

- **\(\pi\)-exchange**

\[
A(\Lambda, n\pi^0) = g(n, n\pi^0) \frac{A_{\Lambda n}}{m_{\Lambda} - m_n} + g(\Lambda, \Sigma^0\pi^0) \frac{A_{\Sigma^0 n}}{m_n - m_{\Sigma^0}}, \quad (13)
\]

\[
A(\Lambda, p\pi^-) = g(n, p\pi^-) \frac{A_{\Lambda n}}{m_{\Lambda} - m_n} + g(\Lambda, \Sigma^+\pi^-) \frac{A_{\Sigma^+ p}}{m_p - m_{\Sigma^+}}. \quad (14)
\]

- **\(\eta\)-exchange**

\[
A(\Lambda, n\eta) = g(n, n\eta) \frac{A_{\Lambda n}}{m_{\Lambda} - m_n} + g(\Lambda, \Lambda\eta) \frac{A_{\Lambda n}}{m_n - m_{\Lambda}}. \quad (15)
\]

- **\(K\)-exchange**

\[
A(n, nK^0) = g(n, \Lambda K^0) \frac{A_{\Lambda n}}{m_n - m_{\Lambda}} + g(n, \Sigma^0K^0) \frac{A_{\Sigma^0 n}}{m_n - m_{\Sigma^0}}, \quad (16)
\]

\[
A(p, pK^0) = g(p, \Sigma^+K^0) \frac{A_{\Sigma^+ p}}{m_p - m_{\Sigma^+}}, \quad (17)
\]

\[
A(p, nK^+) = g(p, \Sigma^0K^+) \frac{A_{\Sigma^0 n}}{m_n - m_{\Sigma^0}} + g(p, \Lambda K^+) \frac{A_{\Lambda n}}{m_n - m_{\Lambda}}, \quad (18)
\]

\[
A(\Lambda, \Lambda K^0) = g(n, \Lambda K^0) \frac{A_{\Lambda n}}{m_{\Lambda} - m_n} + g(\Lambda, \Xi^0K^0) \frac{A_{\Xi^0 n}}{m_{\Lambda} - m_{\Xi^0}}, \quad (19)
\]

\[
A(\Lambda, \Sigma^0K^0) = g(n, \Sigma^0K^0) \frac{A_{\Sigma^0 n}}{m_{\Lambda} - m_n}, \quad (20)
\]

\[
A(\Lambda, \Sigma^-K^+) = g(n, \Sigma^-K^+) \frac{A_{\Lambda n}}{m_{\Lambda} - m_n}. \quad (21)
\]

To compute the former amplitudes, we use the following values for the weak transitions at the baryon lines \(A_{BB'}\):
\[ A_{\Lambda n} \equiv A_{\Lambda N} = -4.32 \times 10^{-5}\text{MeV} , \]
\[ A_{\Sigma^0 n} \equiv -A_{\Sigma N} = 4.35 \times 10^{-5}\text{MeV} , \]
\[ A_{\Xi^0 \Lambda} \equiv A_{\Xi \Lambda} = 5.93 \times 10^{-5}\text{MeV} , \]
\[ A_{\Sigma^+ p} \equiv \sqrt{2} A_{\Sigma N} = -6.15 \times 10^{-5}\text{MeV} . \] (22)

For the vector \( \rho, \omega \) and \( K^* \) mesons one has to make the following replacements in Eqs. (13) to (21):

\[ \pi \rightarrow \rho, \]
\[ \eta \rightarrow \omega, \]
\[ K \rightarrow K^*. \] (23)

**B. Weak PV couplings**

SU(3) allows us to obtain the weak PV couplings involving two baryons and one pseudoscalar \( (\pi, \eta, K) \) meson. In order to obtain the corresponding constants for vector mesons we use SU(6)\(_W\). Here, we quote the results for all the couplings that appear in the \( \Lambda N \rightarrow NN \) and \( \Lambda N \rightarrow YN \) channels.

\[ (\Lambda, p\pi^-)_\text{exp} \equiv \Lambda^0 = 3.25 \times 10^{-7} , \] (24)
\[ (\Sigma^+, p\pi^0)_\text{exp} \equiv \Sigma^+_0 = -3.27 \times 10^{-7} , \] (25)
\[ (\Lambda, n\pi^0) = -\frac{1}{\sqrt{2}} \Lambda^- , \] (26)
\[ (\Lambda, n\rho^0) = \frac{1}{3} (-2\Lambda^- + \sqrt{3} \Sigma^+_0 - \sqrt{3} a_T) , \] (27)
\[ (\Lambda, p\rho^-) = \frac{1}{3} \sqrt{2}(2\sqrt{3}\Lambda^0 - 3\Sigma^+_0 - 3a_V) , \] (28)
\[ (\Lambda, n\eta) = \sqrt{\frac{3}{2}} \Lambda^- , \] (29)
\[ (\Lambda, n\omega) = \Sigma^+_0 - \frac{1}{3} a_T , \] (30)
\[ (n, nK^0) = \sqrt{\frac{3}{2}} \Lambda^- - \frac{1}{\sqrt{2}} \Sigma^+_0 , \] (31)
\[ (p, pK^0) = -\sqrt{2} \Sigma^+_0 , \] (32)
\[ (p, nK^+) = \sqrt{\frac{3}{2}} \Lambda^- + \frac{1}{\sqrt{2}} \Sigma^+_0 , \] (33)
\[ (n, nK^*) = -\sqrt{3}\Lambda^0 - \frac{2}{3} \Sigma^+_0 - \frac{2}{9} a_T , \] (34)
\[ (p, pK^*) = -\frac{2}{3} \Sigma^+_0 + \frac{8}{9} a_T , \] (35)
\[ (p, nK^{*+}) = -\sqrt{3}\Lambda^0 + \frac{10}{9} \Sigma^+_0 + \frac{10}{9} a_V , \] (36)
\[(\Lambda, \Lambda K^0) = -\frac{1}{2} \sqrt{\frac{3}{2}} \Lambda_0^0 - \frac{3}{2\sqrt{2}} \Sigma^+_0, \quad (37)\]
\[(\Lambda, \Sigma^0 K^0) = -\frac{1}{2\sqrt{2}} \Lambda_0^0 - \frac{1}{2} \sqrt{\frac{3}{2}} \Sigma^+_0, \quad (38)\]
\[(\Lambda, \Sigma^- K^+) = \frac{1}{2} \Lambda_0^0 + \frac{\sqrt{3}}{2} \Sigma^+_0, \quad (39)\]
\[(\Lambda, \Lambda K^{*0}) = -\frac{5\sqrt{3}}{6} \Lambda_0^0 - \frac{1}{2} \Sigma^+_0, \quad (40)\]
\[(\Lambda, \Sigma^0 K^{*0}) = \frac{7}{6} \Lambda_0^0 + \frac{3}{2\sqrt{3}} \Sigma^+_0 + \frac{2}{3\sqrt{3}} a_T, \quad (41)\]
\[(\Lambda, \Sigma^- K^{*+}) = -\frac{7}{3\sqrt{2}} \Lambda_0^0 - \frac{3}{\sqrt{6}} \Sigma^+_0 + \frac{4}{3\sqrt{6}} a_V. \quad (42)\]

If we desire only the \(\Delta I = \frac{1}{2}\) part of the above expressions, as we do in the present work, the following replacements have to be made \([30]\):

- For the \(\Lambda N \rho\) couplings: \(a_V \to 3a_V\) and \(a_T \to 3a_T\).
- For the \(\Lambda \Sigma K^*\) couplings: \(a_V \to \frac{a_V - a_T}{\sqrt{3}}\) and \(a_T \to -\frac{a_V - a_T}{\sqrt{3}}\).

**C. Strong coupling constants**

In this subsection we present the convention used for the strong couplings.

\[g_{NN\pi} \equiv g(p, p\pi^0) = -g(n, n\pi^0) = \frac{1}{\sqrt{2}} g(p, n\pi^+) = \frac{1}{\sqrt{2}} g(n, p\pi^-), \quad (43)\]
\[g_{\Lambda \Sigma \pi} \equiv g(\Sigma^+, \Lambda^+) = g(\Sigma^0, \Lambda^0) = g(\Sigma^-, \Lambda^-) = g(\Lambda, \Sigma^+\pi^-) = g(\Lambda, \Sigma^-\pi^+) = \frac{1}{\sqrt{2}} g(p, p\pi^-) = \frac{1}{\sqrt{2}} g(n, n\pi^+), \quad (44)\]
\[g_{N \Lambda K} \equiv g(p, \Lambda K^+) = g(n, \Lambda K^0) = g(\Lambda, pK^-) = g(\Lambda, n\bar{K}^0), \quad (45)\]
\[g_{N \Sigma K} \equiv g(p, \Sigma^0 K^0) = g(\Sigma^0, pK^-) = g(\Sigma^0, n\bar{K}^0) = g(\Sigma^0, n\bar{K}^0) = g(\Sigma^+, n\bar{K}^0) = g(\Sigma^-, nK^-) = \frac{1}{\sqrt{2}} g(p, \Sigma^+ K^0) = \frac{1}{\sqrt{2}} g(n, \Sigma^- K^+) = \frac{1}{\sqrt{2}} g(n, \Sigma^+ K^0) = \frac{1}{\sqrt{2}} g(\Sigma^+, p\bar{K}^0), \quad (46)\]
\[g_{\Lambda \Xi K} \equiv g(\Lambda, \Xi^0 K^0) = g(\Xi^0, \Lambda K^0) = g(\Xi^0, \Lambda K^-) = g(\Xi^-, \Lambda K^+) = -g(\Xi^-, \Lambda K^-) = g(\Xi^-, \Lambda K^+) = -g(\Xi^-, \Lambda K^-), \quad (47)\]
\[g_{NN\eta} \equiv g(n, n\eta) = g(p, p\eta). \quad (48)\]

For the vector \(\rho, \omega\) and \(K^*\) mesons, the expressions are equivalent to the ones quoted above by making the replacements of Eq. (23).

TABLES

TABLE I. Pseudoscalar (PS) and vector (V) hamiltonians entering Eq. (8) (in units of $G_F m_\pi^2 = 2.21 \times 10^{-7}$). $\Psi$ ($\Phi$) stands for the baryon (meson) field.

| PS          | V                      |
|-------------|------------------------|
| Strong      | $i g \bar{\Psi} \gamma_5 \phi \Psi$ | $\bar{\Psi} \left[ g V^\mu \gamma^\mu + i g T \sigma^{\mu\nu} q_\nu \right] \phi \Psi$ |
| Weak        | $i \bar{\Psi} (A + B \gamma_5) \phi \Psi$ | $\bar{\Psi} \left[ \alpha \gamma^\mu - \beta \sigma^{\mu\nu} q_\nu + \epsilon \gamma^\mu \gamma_5 \right] \phi \Psi$ |

TABLE II. Possible $2S+1L_J$ channels present in the weak decay of $^6\Lambda\Lambda$ He. The notation used is the following: $L_r$ stands for the relative orbital momentum for the initial $\Lambda\Lambda$ or $\Lambda N$ pair, $L'$ for the relative angular momentum of the two-particle state right after the weak transition occurs, and $L$ for the relative angular momentum of the final two-particle state after including the effects of the strong interaction (FSI). The symbols C, T and PV stand for Central, Tensor and Parity Violating.

| | $\Lambda p \rightarrow np$ | $\Lambda n \rightarrow nn$ | $\Lambda\Lambda \rightarrow YN$ |
|---|---|---|---|
| | $L_r$ | $L'$ | $L$ | $L_r$ | $L'$ | $L$ | $L_r$ | $L'$ | $L$ |
| C | $^1S_0 \rightarrow ^1S_0 \rightarrow ^1S_0$ | $^1S_0 \rightarrow ^1S_0 \rightarrow ^1S_0$ | $^1S_0 \rightarrow ^1S_0 \rightarrow ^1S_0$ |
| | $^3S_1 \rightarrow ^3S_1 \rightarrow ^3S_1, ^3D_1$ | $^1S_0 \rightarrow ^3S_0 \rightarrow ^3S_0$ | $^1S_0 \rightarrow ^3S_0 \rightarrow ^3S_0$ |
| T | $^3S_1 \rightarrow ^3D_1 \rightarrow ^3D_1, ^3S_1$ | $^1S_0 \rightarrow ^3S_0 \rightarrow ^3S_0$ | $^1S_0 \rightarrow ^3S_0 \rightarrow ^3S_0$ |
| PV | $^1S_0 \rightarrow ^3P_0 \rightarrow ^3P_0$ | $^1S_0 \rightarrow ^3P_0 \rightarrow ^3P_0$ | $^1S_0 \rightarrow ^3P_0 \rightarrow ^3P_0$ |
| | $^3S_1 \rightarrow ^1P_1 \rightarrow ^1P_1$ | $^3S_1 \rightarrow ^1P_1 \rightarrow ^1P_1$ | $^3S_1 \rightarrow ^1P_1 \rightarrow ^1P_1$ |
| | $^3S_1 \rightarrow ^3P_1 \rightarrow ^3P_1$ | $^3S_1 \rightarrow ^3P_1 \rightarrow ^3P_1$ | $^3S_1 \rightarrow ^3P_1 \rightarrow ^3P_1$ |

TABLE VI. Individual and combined meson-exchange contributions to the nonmesonic weak decay of $^6\Lambda\Lambda$He. Strong correlations (initial and final) and FF are included. The nonmesonic decay rate is in units of $\Gamma_\Lambda = 3.8 \times 10^9\text{s}^{-1}$. The NSC97f [11] strong interaction model has been used. The values between parenthesis have been obtained using the weak kaon couplings from Refs. [28, 29].

| Meson | $\Gamma_{\text{NN}}$ | $\Gamma_{\text{np}}$ | $\Gamma_n/\Gamma_p$ | $\Gamma_\Lambda$ | $\Gamma_{\Sigma N}^n$ | $\Gamma_{\Sigma N}^{-p}$ | $\Gamma_{\text{NN}} + \Gamma_{\text{YN}}$ |
|-------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| $\pi$  | $2.6 \times 10^{-2}$ | $0.50$           | $2.6 \times 10^{-2}$ | $1.2 \times 10^{-3}$ | $2.3 \times 10^{-3}$ | $2.3 \times 10^{-3}$ | $0.75$           |
| $\pi + K$ | $2.7 \times 10^{-2}$ | $0.61$           | $1.7 \times 10^{-2}$ | $1.1 \times 10^{-3}$ | $2.3 \times 10^{-3}$ | $2.3 \times 10^{-3}$ | $0.73$           |
| $\pi + K + \eta$ | $3.58 \times 10^{-2}$ | $0.46$           | $1.9 \times 10^{-2}$ | $1.0 \times 10^{-3}$ | $2.0 \times 10^{-3}$ | $2.0 \times 10^{-3}$ | $1.00$           |
TABLE VII. Decay rate of $^6\Lambda\Lambda$He in units of $\Gamma_\Lambda = 3.8 \times 10^9 s^{-1}$ for different approaches to FSI. All mesons are included in the calculation.

|                | $\Gamma_{\text{NN}}$ | $\Gamma_{\text{AN}}$ | $\Gamma_{\Sigma N}$ | $\Gamma_{\text{NN} + \Gamma_{\text{YN}}}$ |
|----------------|----------------------|----------------------|----------------------|----------------------------------------|
| NO FSI       | $\Gamma_{\text{nn}}$ | $\Gamma_{\text{np}}$ | $\Gamma_{\Sigma \text{p}}$ | $\Gamma_{\Sigma \text{n}}$ |
| 0.69          | 1.21                 | 0.57                 | $2.5 \times 10^{-3}$    | $1.1 \times 10^{-2}$  | $2.2 \times 10^{-2}$ | 1.93 |
| FSI eff.     | 0.73                 | 1.30                 | $4.4 \times 10^{-3}$    | $8.0 \times 10^{-3}$  | $1.6 \times 10^{-2}$ | 2.03 |
| $\Gamma$-matrix | 0.30                | 0.66                 | $3.6 \times 10^{-2}$    | $1.0 \times 10^{-3}$  | $2.0 \times 10^{-3}$ | 1.00 |

TABLE VIII. $\chi$PT one-loop corrected NNK, $\Lambda\Lambda K$ and $\Lambda\Sigma K$ couplings. Values taken from Refs. [28,29].

|                | $S$-wave | $P$-wave |
|----------------|----------|----------|
| pnK$^+$        | $(0.32 \pm 0.24)$ | $(-10.41 \pm 1.61)$ |
| ppK$^0$        | $(2.32 \pm 0.22)$ | $(3.47 \pm 2.23)$ |
| nnK$^0$        | $(2.64 \pm 0.25)$ | $(-6.94 \pm 2.23)$ |
| $\Lambda\Lambda K$ | $(0.78 \pm 0.20)$ | $(8.69 \pm 2.21)$ |
| $\Lambda\Sigma$ | $(0.53 \pm 0.12)$ | $(-0.58 \pm 1.83)$ |
| $\Lambda\Sigma - K^+$ | $(-0.75 \pm 0.17)$ | $(0.82 \pm 2.59)$ |

TABLE IX. Partial weak decay rates for $^6\Lambda\Lambda$He (in units of $\Gamma_\Lambda = 3.8 \times 10^9 s^{-1}$).

|                | NSC97f       | NSC97f + one-loop corrections |
|----------------|--------------|-----------------------------|
| $\Lambda n \to \text{nn}$ | 0.30    | 0.25 $\pm$ 15 $\%$ |
| $\Lambda p \to \text{np}$ | 0.66  | 1.13 $\pm$ 15 $\%$ |
| $\Lambda N \to \text{NN}$ | 0.96 | 1.38 $\pm$ 15 $\%$ |
| $\Gamma_{\text{n}}/\Gamma_p$ | 0.46 | 0.23 $\pm$ 20 $\%$ |
| $\Lambda\Lambda \to \Lambda n$ | $3.6 \times 10^{-2}$ | $1.2 \times 10^{-2} \pm 50 \%$ |
| $\Lambda\Lambda \to \Sigma^0 n$ | $1.0 \times 10^{-3}$ | $1.7 \times 10^{-3} \pm 30 \%$ |
| $\Lambda\Lambda \to \Sigma^- p$ | $2.0 \times 10^{-3}$ | $3.4 \times 10^{-3} \pm 30 \%$ |
| $\Lambda\Lambda \to \text{YN}$ | $3.9 \times 10^{-2}$ | $1.7 \times 10^{-2} \pm 30 \%$ |
FIG. 1. Feynman diagram for the weak $\Lambda N \rightarrow NN$ and $\Lambda\Lambda \rightarrow YN$ ($\Sigma N$ or $\Lambda n$ interaction).

FIG. 2. Probability per unit length of finding two $\Lambda$'s at a relative distance $r$.
