ABSTRACT

We verify numerically that in the context of general relativity (GR), flat models which have the same $\Omega_m$ and CMB shift parameter $R$ but different $H(a)$ and $w(a)$ also have very similar (within less than 8%) growth of perturbations even though the dark energy density evolution is quite different. This provides a direct connection between geometrical and dynamical tests of dark energy and may be used as a cosmological test of general relativity.

Keywords: cosmology:large-scale structure of universe

1 INTRODUCTION

There is by now convincing evidence that the available high quality cosmological data (Type Ia supernovae, CMB, etc.) are well fitted by an emerging “standard model”. In the context of GR this “standard model”, assuming flatness, is described by the Friedman equation

$$H^2(a) = \left(\frac{\dot{a}}{a}\right)^2 = H_0^2 \left[ \Omega_m(a) + \Omega_{DE}(a) \right]$$

where $a(t)$ is the scale factor of the universe, $\Omega_m(a)$ is the density parameter corresponding to the sum of baryonic and cold dark matter, with the latter needed to explain clustering, and an extra component $\Omega_{DE}(a)$ with negative pressure called dark energy needed to explain the observed accelerated cosmic expansion (Riess et al. 1998; Perlmutter et al. 1999; Efstathiou et al. 2002; Tegmark et al. 2004; Spergel et al. 2002; Nesseris & Perivolaropoulos 2005; Nesseris & Perivolaropoulos 2007a). During the last decade there have been many theoretical speculations regarding the nature of the exotic “dark energy”. Various candidates have been proposed in the literature, among which a dynamical scalar field acting as vacuum energy (Ozer & Taha 1987; Caldwell, Dave & Steinhardt 1998; Peebles & Ratra 2003). Under this framework, high energy field theories generally indicate that the equation of state of such a dark energy is a function of the cosmic time. To identify this type of evolution of the equation of state, a detailed form of the observed $H(z)$ is required which may be obtained by a combination of multiple dark energy probes. Such probes may be divided in two classes according to the methods used to obtain $H(z)$.

- Geometric methods probe the large scale geometry of space-time directly through the redshift dependence of cosmological distances [$d_L(z)$ or $d_A(z)$]. They thus determine $H(z)$ independent of the validity of Einstein equations.

- Dynamical methods determine $H(z)$ by measuring the evolution of energy density (background or perturbations) and using a gravity theory to relate them with geometry ie with $H(z)$. These methods rely on knowledge of the dynamical equations that connect geometry with energy and may therefore be used in combination with geometric methods to test these dynamical equations.

A very accurate and deep geometrical probe of dark energy is the angular scale of the sound horizon at the last scattering surface as encoded in the location $l_{TT}^i$ of the first peak of the Cosmic Microwave Background (CMB) temperature perturbation spectrum. This probe is described by the so called CMB shift parameter (cf. Bond, Efstathiou & Tegmark 1997; Trotta 2004; Nesseris & Perivolaropoulos 2007) which is defined as
Figure 1. The locus of $w_0$, $w_1$ for Case 1 (solid line), Case 2 (dotted line), Case 3 (circle, see text), Case 4 ($m = 2$, $n = 0$ short dashed line) and Case 4 ($m = 1$, $n = 1$ long dashed line).

$R = \frac{l_{TT}'}{l_{TT}}$  \hspace{1cm} (2)

where $l_{TT}'$ is the temperature perturbation CMB spectrum multipole of the first acoustic peak. In the definition of $R$, $l_{TT}'$ corresponds to the model (with fixed $\Omega_m$, $\Omega_b$ and $h$) characterized by the shift parameter and $l_{TT}$ to a reference flat SCDM model ($\Omega_m = 1$) with the same $\omega_m = \Omega_m h^2$ and $\omega_b = \Omega_b h^2$ as the original model. Recently, Nesseris & Perivolaropoulos (2007) have found that models based on general relativity that have identical shift parameter $R$ and matter density $\Omega_m$ also lead to almost identical ISW effect despite of their possible differences in the cosmic expansion histories.

The aim of this work is to investigate our suspicion that the (geometrical) CMB shift parameter is somehow associated with the (dynamical) fluctuation growth rate in the context of general relativity. Note, that a possible violation of this connection may thus be viewed as a hint for modifications of general relativity. The structure of the paper is as follows. The basic theoretical elements are presented in section 2. The results are presented in section 3 by solving numerically the time evolution equation for the mass density contrast for various flat dark energy models that share the same value of shift parameter and value of $\Omega_m$. In section 4 we draw our conclusions. Finally, in the appendix we have treated analytically, up to a certain point, the differential equation for the mass density contrast considering different dark energy models with a time varying equation of state.

2 THEORETICAL ELEMENTS

The location $l_{TT}'$ of the first acoustic peak in the CMB temperature spectrum can be connected with the angular diameter distance $d_A$ and with the sound horizon $r_s$ both at the last scattering surface ($z = z_{ls}$) and then the shift parameter (see Nesseris & Perivolaropoulos 2007 and references therein for details) can be brought to the form $R' = \sqrt{\Omega_m} \int_{z_{ls}}^{0} \frac{dz}{E(z)}$. The expression usually used for the shift parameter is

$$R = \sqrt{\Omega_m} \int_{a_{ls}}^{1} \frac{da}{a^2 H(a)/H_0} = \sqrt{\Omega_m} \int_{0}^{z_{ls}} \frac{dz}{E(z)} \hspace{1cm} (3)$$

where $E(z) \equiv H(z)/H_0$.

In order to define $E(z)$ we use the Chevalier-Polarski-Linder (CPL) [Chevallier & Polarski 2001; Linder 2003] parametrization for which

$$w(a) = w_0 + w_1 (1 - a) \hspace{1cm} (4)$$

and

$$E^2(a) = \Omega_m a^{-3} + \frac{(1 - \Omega_m)a^{-3}}{f(a)} \hspace{1cm} (5)$$

where

$$f(a) = \exp \left[ -3 \int_{a}^{1} \frac{w(u)}{u} du \right] = a^{3(w_0 + w_1)} e^{-3w_1(a - 1)} \hspace{1cm} (6)$$

On the other hand, a dynamical probe of geometry is the measured linear growth factor of the matter density perturbations $\delta(a)$. The evolution equation of the growth factor for models where the dark energy fluid has a vanishing anisotropic stress and the matter fluid is not coupled to other matter species is given by (Peebles 2003; Stabenau & Jain 2006; Uzan 2007):
\[ \dot{\delta} + 2H(t)\delta - 4\pi G\rho_m \delta = 0 \]  
\hspace{1cm} (7)

where dots denote derivatives with respect to time. Useful expressions of the growth factor can be found for the \( \Lambda \)CDM cosmology in Peebles (1993) and for the quintessence scenario (\( w = \text{const} \)) in Silveira & Waga (1994), Wang & Steinhardt (1998), Basilakos (2003), Nesseris & Perivolaropoulos (2008) and for the scalar tensor models in Gannouji & Polarski (2008). As an example, in the case of \( \Lambda \)CDM cosmology the growth factor is of the form

\[ \delta(a) = \frac{5\Omega_m H(a)}{2} \int_0^a \frac{da'}{(a'H(a'))^2} \]  
\hspace{1cm} (8)

which for \( a = 1 \) has some similarity with the form of the shift parameter (see eq.3). Finally, it is interesting to mention here that for dark energy models with a time varying equation of state (see next section).

\[ m \] is the CMB shift parameter. 

BY NOT NORMALIZE THE GROWTH FACTOR WITH ITS VALUE AT \( a = 1 \) AS WE ARE INTERESTED IN ITS RANGE OF VALUES AT \( z = 0 \).

\[ \text{Figure 2. The growth factor for the first three cases and all Monte-Carlo values of } w_0 \text{ and } w_1 (\Omega_m = 0.25). \text{ Case 1 corresponds to Fig.2a and cases 2 and 3 to Fig.2b and Fig.2c respectively. Note that for this figure we do not normalize the growth factor with its value at } a = 1 \text{ as we are interested in its range of values at } z = 0. \]

\[ \delta + 2H(t)\delta - 4\pi G\rho_m \delta = 0 \]

\hspace{1cm} (7)

where dots denote derivatives with respect to time. Useful expressions of the growth factor can be found for the \( \Lambda \)CDM cosmology in Peebles (1993) and for the quintessence scenario (\( w = \text{const} \)) in Silveira & Waga (1994), Wang & Steinhardt (1998), Basilakos (2003), Nesseris & Perivolaropoulos (2008) and for the scalar tensor models in Gannouji & Polarski (2008). As an example, in the case of \( \Lambda \)CDM cosmology the growth factor is of the form

\[ \delta(a) = \frac{5\Omega_m H(a)}{2} \int_0^a \frac{da'}{(a'H(a'))^2} \]  
\hspace{1cm} (8)

which for \( a = 1 \) has some similarity with the form of the shift parameter (see eq.3). Finally, it is interesting to mention here that for dark energy models with a time varying equation of state, an analytical solution for \( \delta(a) \) has yet to be found because the basic differential equation (7) becomes more complicated than in models with constant \( w \). However, in a recent paper (Linder & Cahn 2007) a growth index \( \gamma \) was used to parameterize the linear growing mode including models with a time varying equation of state (see next section).

3 THE CONNECTION BETWEEN THE CMB SHIFT PARAMETER AND THE GROWTH FACTOR

In order to explore the above mentioned connection of the CMB shift parameter \( R \) of eq. (3) with the growth factor \( \delta(a) \), we perform a Monte-Carlo analysis in the parameter space of \( w_0 \) and \( w_1 \) of the parametrization (4). In particular we fix \( \Omega_m \) (for example 0.25) and compare the variation of the growth factor for \( w_0 \) and \( w_1 \) pairs corresponding to fixed \( R \) with the corresponding variation when other combinations of \( w_0 \) and \( w_1 \) are fixed. Specifically, we consider and compare 4 cases:

- Case 1: \( w_0 \) and \( w_1 \) are constrained by a fixed value of the CMB shift parameter, \( R(w_0, w_1) = 1.7 \)
- Case 2: \( w_0 \) and \( w_1 \) are constrained by a linear relation of the form \( w_1 = -2.9 - 3.1w_0 \) approximating the locus of the \( w_0 \) and \( w_1 \) that satisfy the relation \( R(w_0, w_1) = 1.7 \) (see Fig.1). This approximation is accurate to within about 5% and provides an estimate of the uncertainties introduced in the predicted value of the growth factor if the shift parameter is not accurately measured.
- Case 3: \( w_0 \) and \( w_1 \) are constrained to be on a circle of radius 0.5 and center the \( \Lambda \)CDM point (-1,0)
- Case 4: \( w_0 \) and \( w_1 \) are constrained by a fixed value of an integral ansatz of a form similar to the CMB shift parameter

\[ A(w_0, w_1)_{m,n} = \sqrt{\Omega_m} \int_0^{z_{ls}} \frac{dz}{(1 + z)^n E^m(z)} \]  
\hspace{1cm} (9)

for various values of the parameters \( m, n \) (see Table 1). Note that for \( (m, n) = (1,0) \) we get the usual CMB shift parameter.

In the first two cases \( w_0 \) is a random variable in the range \([-1.5, -0.5]\) and for each value of \( w_0 \) we use the constraint equation to solve for \( w_1 \). In case 3, \( w_0 \) and \( w_1 \) are on a circle of radius 0.5 and center the \( \Lambda \)CDM point (-1,0). In Fig.1 we show the locus of the points \( w_0 \) and \( w_1 \) that satisfy the constraints of cases 1-4. Notice that in Fig. 1, case 3 is shown as an ellipse and not a circle due to the fact that the aspect ratio is chosen so that the loci for the other cases are shown optimally. Also, in Fig.2 we present the growth factor evolution which is derived by solving numerically eq. (7), for the first three cases and all Monte-Carlo values of \( w_0 \) and \( w_1 \) (100 pairs each time). In case 1 the values of \( \delta(a = 1) \) are much more constrained than the other two cases as the range (dispersion) of the growth factor at \( a = 1 \), ie \( \max[\delta(a = 1)] - \min[\delta(a = 1)] \), for the
first case is 0.055 (corresponding to a variation of the mean value of \( \delta(a = 1) \) of less than 8%) while in the second and third cases it is 3.1 (33% variation) and 5.9 (49% variation) times that value. We have also investigated the sensitivity of our analysis to the matter density parameter. In particular, we confirmed that in the range \( \Omega_m \in [0.2, 0.3] \) our results depend weakly on the value of \( \Omega_m \). In fact, the present time dispersion of the growth factor for fixed shift parameter varies from 3.5% for \( \Omega_m = 0.2 \) to 9% for \( \Omega_m = 0.3 \) (8% for \( \Omega_m = 0.25 \)). Thus our main result persists for all physical values of \( \Omega_m \) and it strongly indicates that the CMB shift parameter is somehow associated with the growth factor in the context of general relativity.

The linear relation of the form \( w_1 = -2.9 - 3.1w_0 \) corresponding to Fig. 2b provides a rough approximation (good to about 5%) of the locus of points that satisfy the relation \( R(w_0, w_1) = 1.7 \). This introduces significant additional dispersion to the present day growth factor (the dispersion goes to 33% in Fig. 2b from the 8% obtained with the exact locus of fixed \( R \) in Fig. 2a). Once we improve the \( w_1 \) expression with an appropriate quadratic term in \( w_0 \), the approximation improves from about 5% to about 0.3% and the growth factor dispersion drops back to 8.5% (almost the same as with the exact locus of fixed \( R \)). This is an interesting result as it means that the shift parameter should be measured with 1σ errors better than 1% for a determination of the growth factor to an accuracy better than 10%. This accuracy of measurement of the shift parameter however is not far from present day measurements which have determined \( R \) to within 1.5% (\( R = 1.7 \pm 0.03 \) from Wang & Mukherjee 2007).

In case 4 the analysis is similar to case 1, ie \( w_0 \) is a random variable but now \( w_1 \) is found from the generalized constraint

\[
A(w_0, w_1)_{m,n} = A_{fixed \, m,n}
\]  

(10)

where \( A_{fixed \, m,n} \) is the value of \( A(w_0, w_1)_{m,n} \) for a \( \Lambda \)CDM cosmology (\( w_0 = -1, w_1 = 0 \)) for the respective values of \( m, n \). We computed the range (dispersion) of the growth factor at \( a = 1 \), ie \( Max[\delta(a = 1)] - Min[\delta(a = 1)] \) for the values \( w_0 \) and \( w_1 \) derived from the constraint eq. (10). In Table 1 we show the ratio of these values for various \( m, n \) to the value of the range of the growth factor for \( m = 1, n = 0 \). The case \( m = 1, n = 0 \) corresponds to the CMB shift parameter. Notice that for these values of \( m, n \) the ratio becomes minimal.

Finally, we checked that random values for both \( w_0 \) and \( w_1 \) give a much larger dispersion on the values of \( \delta(a = 1) \), as exactly they should. Notice that the CMB shift parameter \( R (m = 1, n = 0) \) seems to constrain the growth factor by about an order of magnitude or more compared to other forms of the integral ansatz (different values of \( m \) and \( n \)). From a theoretical point of view a possible relation between the CMB shift parameter and the growth factor can be used as a viable test for the general relativity. As expected (Bertschinger 2006), changing the validity of Einstein’s field equations (the so called theory of modified gravity), we change accordingly the growth factor [see Gannouji & Polarski (2008) for a detailed investigation of the growth factor in scalar-tensor theories]. In contrast the behavior of the CMB shift parameter remains unaltered, simply because the latter is a geometrical function (see e.g. Nesseris & Perivolaropoulos 2007). Thus, a mismatch between the measured value of the shift parameter and the measured value of the linear growth factor would be a hint towards modified gravity.

Verifying this connection between the growth factor and the CMB shift parameter \( R \) analytically requires an exact or approximate solution to the differential equation for the evolution of density perturbations when evolving dark energy is taken into account. In what follows we discuss some recent attempts towards the construction of such approximate solutions.

A well known approximate solution to eq.(7) is found by Linder & Cahn (2007), where a growth index \( \gamma \) was used to parameterize the linear growing mode for models with a time varying equation of state. Specifically, the growth index \( \gamma \) was defined through

\[
D(a) = \exp \left[ \int_1^a \frac{\Omega_m(u)}{u} \, du \right]
\]

(12)

where \( D(a) \) is the growth factor normalized to unity and it was found that \( \gamma \) can be approximated by

\[
\gamma = \frac{6 - 3(1 + w_\infty)}{1 - 6(1 + w_\infty)}
\]

(13)

\( w_\infty \equiv w(z \gg 1) \).
The previous approach was based on the approximation that the universe is not too far from being matter-dominated. However, by utilizing just some basic elements from the differential equation theory we have solved analytically up to a certain point (see the Appendix for details), assuming that the equation of state parameter is a function of time. In this approach the growing $D_+(a)$ and decaying $D_-(a)$ modes are given by

$$D_\pm(a) \simeq a^{-3/2} E^{-1/2}(a) \exp\left(\mp \frac{\sqrt{2} T}{3} \int_{1}^{a} |g(u)|^{1/2} du\right)$$

where $g(a)$ is defined in the Appendix.

Utilizing the best-fit cosmological parameters $\Omega_m = 0.25$ and $(w_0, w_1) = (-0.95, 0.43)$ obtained from the Gold06 SNIa dataset and the CMB shift parameter, in the right panel of Fig. 3, we present the approximated growth factor (left panel), as a function of redshift by utilizing eq. (14) (solid line) and eq. (12) respectively (dashed line). It is obvious that our analytical approximation is indeed close to that found by Linder & Cahn (2007). In the right panel of Fig. 3 we show the percent accuracy ($1 - D_{\text{appr}}/D_{\text{num}}$)% of the two approximations $D_{\text{appr}}$, compared to the numerical solution. Eq. (12) deviates from the numerical solution by 0.17% while our $D_+(z)$ approximation deviates by $0.5 - 1.1%$.

4 CONCLUSIONS

In this work, we found that flat models which have the same $\Omega_m$ and CMB shift parameter $R$ but different $H(a)$ and $w(a)$ also have very similar growth of perturbations even though the dark energy density evolution is quite different. This was done by comparing various forms of constraints for $w_0$ and $w_1$, besides the CMB shift parameter, by a Monte-Carlo simulation. In all cases considered, models constrained by the CMB shift parameter had also a very similar growth factor.

APPENDIX

In this appendix we try to treat analytically, as much as possible, the problem of the growth factor evolution for dark energy models with a time varying equation of state.

The time evolution equation for the mass density contrast, modeled as a pressureless fluid, is obtained from the Euler and matter stress energy conservation equations as:

$$\ddot{\delta} + 2H(t)\dot{\delta} - 4\pi G\rho_m\delta = 0$$

where dots denote derivatives with respect to time. This differential equation is valid for models where the dark energy fluid has a vanishing anisotropic stress and the matter fluid is not coupled to other matter species, however see Uzan (2007) for a detailed discussion of the modifications that appear on the right-hand side of the above equation when such terms are present. Changing variables from $t$ to $a$ the above equation becomes (see also Linder 2003)

$$\delta'' + A(a)\delta' + B(a)\delta = 0$$

where $A(a) = \frac{3}{2a^2} \left[1 - \frac{(1 - \Omega_m)w(a)}{1 - \Omega_m + \Omega_m f(a)}\right]$ and $B(a) = -\frac{3}{2a^2} \left[\frac{\Omega_m f(a)}{1 - \Omega_m + \Omega_m f(a)}\right]$. Performing now the following transformation

$$\delta(a) = y(a) \exp \left(-\frac{1}{2} \int_{1}^{a} A(u) du\right)$$
the linear mass density fluctuations is written:
\[
\delta(a) = y(a) a^{-3/2} E^{-1/2}(a)
\]  
and the unknown function \( y \) satisfies the following differential equation:
\[
y'' - g(a)y = 0
\]
with a relevant factor of
\[
g(a) = \frac{1}{2} A'(a) + \frac{1}{4} A^2(a) - B(a) .
\]
It becomes evident, that a major part of the solution is described by the expression \( a^{-3/2} E^{-1/2}(a) \).

Of course, in order to solve fully the problem we have to derive the functional form of \( y \). In particular, we write eq. (19) as follows
\[
\frac{y'^2}{2} - \frac{g(a)y^2}{2} + \int_1^a \frac{y^2(u)}{2} g'(u) du = -c_1
\]
or
\[
|g(a)y^2| = |c^2 + \int_1^a y^2(u) g'(u) du + y^2| \quad (c^2 = 2c_1)
\]
From a mathematical point of view we can select the integration constant \( c \) to be large enough such as
\[
n^2 |g(a)|y^2 \leq n^2 c^2 + \int_1^a n^2 |g(u)|y^2(u) \frac{|g'(u)|}{|g(u)|} du + y^2
\]
where \( n^2 \) is the normalization constant of the problem. Now, we can use Gronwall’s theorem (see Gronwall 1919), which is a well known theorem from the differential equation theory.

**Theorem:** Let assume that \( \mu : [a, \beta] \rightarrow [0, \infty) \) and \( y : [a, \beta] \rightarrow [0, \infty) \) continuous functions and \( \lambda \in \mathbb{R} \). If
\[
y \leq \lambda + |\int_{t_0}^t \mu(x) y(x) dx| \quad \forall t \in [a, \beta]
\]
then
\[
y \leq \lambda \exp \left( \int_{t_0}^t \mu(x) dx \right) \quad \forall t \in [a, \beta]
\]
and using it on (23) we get the following useful formula:
\[
n^2 |g(a)|y^2 \leq n^2 c^2 \exp \left( \int_1^a \frac{|g'(u)|}{|g(u)|} du \right) + y^2 .
\]
Doing so it turns out that a possible approximation could be:
\[
n^2 |g(a)|y^2 \simeq n^2 c^2 |g(a)| + y^2
\]
from which we get that:
\[
y(a) \simeq c \cosh \left( \pm n \int_1^a |g(u)|^{1/2} du \right) .
\]
Taking into account eq. (18), we can obtain the following approximation:
\[
\delta(a) \simeq c a^{-3/2} E^{-1/2}(a) \cosh \left( \pm n \int_1^a |g(u)|^{1/2} du \right) .
\]
In order to normalize our analytical expression we use as a limiting case the Einstein de-Sitter model \( (\Omega_m = 1, g(a) = 21/16a^2) \) in which the behavior of the corresponding growing mode is well known \( D_+(a) = a \).
Indeed, doing so we get \( n = \sqrt{21}/3 \) and thus, the following normalized growing \( D_+ \) and decaying \( D_- \) modes respectively become:
\[
D_+(a) \simeq a^{-3/2} E^{-1/2}(a) \exp \left( \mp \sqrt{21}/3 \int_1^a |g(u)|^{1/2} du \right)
\]
