Multivariate chemogenomic screening prioritizes new macrofilaricidal leads

Nicolas J. Wheeler, Kaetlyn T. Ryan, Kendra J. Gallo, Clair R. Henthorn, Spencer S. Ericksen, John D. Chan & Mostafa Zamanian

Development of direct acting macrofilaricides for the treatment of human filariases is hampered by limitations in screening throughput imposed by the parasite life cycle. In vitro adult screens typically assess single phenotypes without prior enrichment for chemicals with antifilarial potential. We developed a multivariate screen that identified dozens of compounds with submicromolar macrofilaricidal activity, achieving a hit rate of >50% by leveraging abundantly accessible microfilariae. Adult assays were multiplexed to thoroughly characterize compound activity across relevant parasite fitness traits, including neuromuscular control, fecundity, metabolism, and viability. Seventeen compounds from a diverse chemogenomic library elicited strong effects on at least one adult trait, with differential potency against microfilariae and adults. Our screen identified five compounds with high potency against adults but low potency or slow-acting microfilaricidal effects, at least one of which acts through a novel mechanism. We show that the use of microfilariae in a primary screen outperforms model nematode developmental assays and virtual screening of protein structures inferred with deep learning. These data provide new leads for drug development, and the high-content and multiplex assays set a new foundation for antifilarial discovery.
helminths infect billions of humans, livestock, and companion animals around the world. Vector-borne filarial parasitic nematodes cause two neglected tropical diseases (onchocerciasis and lymphatic filariasis (LF)), human loiasis and mansoniellosis, canine heartworm disease, and various infections of large animals, collectively causing profound devastation across the globe. The portfolio of antifilarials clears the circulating arthropod-infected microfilariae (mf); however, these drugs do not clear adult worms when used alone, and some are contraindicated in regions that are co-endemic for multiple filarial nematode species. Some macrofilaricides, such as melarsomine, have been used in veterinary medicine to clear adult heartworm infections, but the high toxicity makes them unsuitable for humans. Concurrent growth of antifilarial use in human medicine, resistance in veterinary medicine, and the paucity of new therapeutic leads present a need for innovation in antifilarial development. Macrofilaricides to treat clinical filariasis cases or sterilizing compounds to interrupt disease transmission are urgently needed.

Screening disease-relevant phenotypes to identify antifilarials is complicated by a number of experimental and biological factors. Screens against adults are particularly encumbered and costly due to their large size, two-host life cycle, and low yield in animal models. In adulticide screening regimens, drug responses are typically measured using single-phenotype in vitro assays that are low in resolution and information. Moreover, the extreme phenotypic heterogeneity among infection cohorts and individual ex vivo parasites makes assays highly variable. Despite these limitations, there are unrealized opportunities to capture more robust and disease-relevant phenotypic information from individual adult parasites.

An additional opportunity is found in the abundance of mf, which can be isolated in batches of tens of millions from rodent hosts. It is conceivable that a high-throughput primary screen against mf could enrich for compounds with bioactivity against adults. Indeed, >90% of the ~11,000 genes expressed in adults are also expressed in mf (Supplementary Table 1). Measuring a range of emergent phenotypes in this abundantly accessible prelarval stage may allow for predictions of general activity against adults. Because chemical perturbation of a common target does not guarantee a conserved phenotypic response in distinct life stages, multivariate screens may help associate disparate drug response phenotypes. For instance, ivermectin diminishes protein secretion by mf and reduces fecundity and motility in adults, the contrasts resulting from stage-specific physiological roles and discrepant patterns of receptor localization. Multivariate screens with multiple time points could further enhance these strategies by characterizing in vitro pharmacodynamics, which may have an impact on host toxicity.

To test these ideas and advance macrofilaricide discovery, we selected a diverse compound library that would allow the exploration of the phenotypic space of mf and adults by targeting classically druggable proteins (Fig. 1a). As a chemogenomic library, each compound in the library is linked to a validated human target, positioning them as molecular probes to discover and validate targets in parasites. In contrast to repurposing screens, the emphasis of a chemogenomic approach is on target discovery in addition to chemical matter. We expect that a subset of compounds with desirable antifilarial properties act through parasite proteins that can be selectively targeted (Fig. 1b). This library was used in a bivariate primary screen against mf, and hit compounds were diverted to a secondary, multivariate screen against adults that parallelized an array of phenotypic endpoints (Fig. 1c). To inform future anthelmintic screening efforts, we also evaluated the utility of C. elegans as a model for antifilarial discovery and the predictive power of virtual screening against human and parasite protein structures modeled by deep learning. We show that tiered, multivariate phenotyping greatly increases the efficiency of hit discovery in macrofilaricide screens and more thoroughly characterizes the bioactivity of lead compounds, resulting in the identification of more than a dozen compounds with submicromolar potency against filarial adults. This strategy, leveraging the unique capacities of distinct parasite stages, could be deployed in other areas of anthelmintic and target discovery.

Results
Development of a high-throughput, bivariate microfilariae screen. We developed a bivariate (motility and viability) primary screen that assayed compound activity on microfilariae (mf) at two time points over 36 h (Fig. 2a–f). We used a high concentration (100 μM) of a diverse compound library to stretch the phenotypic space of mf and allow optimization of a number of different screening parameters, including assay timeline, assay plate design, mf preparation and seeding density, imaging specifications, and image and data processing. Handling and imaging parameters were codified to account for a variety of environmental stimuli that affected mf behavior in plates, including ambient light, room and assay chamber temperature, humidity, settling time prior to imaging, shake speed prior to imaging, and the use of a plate sealer (Supplementary Fig. 1). Deep optimization of imaging-based screens such as this is important for reproducibility across time and space.

Parasites from different batches have varying degrees of health and purity, which reduce the signal to noise ratio of the viability assay. We incorporated a column filtration of healthy mf, which substantially cleaned the mf preparations and reduced noise (Fig. 2c). In our initial optimization experiments, we used sodium azide as a positive control, which had been previously used for viability assays with C. elegans. However, 50 mM sodium azide paralyzed but did not kill mf, so heat-killed mf were the positive control for all future assays (Fig. 2c).

Initial motility recordings included 40 frames over 15 s per well, resulting in a ~25 min total acquisition time per plate and a nearly 2x difference in raw motility between the wells at the beginning and end of the plates, caused by mf congregation over time (Fig. 2a). We subsampled data from assay plates and found that the motility calculations from subsampled videos were highly correlated (ρ > 0.99, Fig. 2b). We chose to acquire 10 frames for each well, reducing the acquisition time and parasite congregation without loss of information. Future motility data was also normalized using the segmented worm area so wells with more worms did not have a resultant higher motility value, and experiments employed a plate design with staggered controls, allowing for regression of values from treatment wells to a line fit across control wells. These acquisition and normalization methods greatly reduced the data variability (Fig. 2d). The final optimized screening strategy included motility measurement 12 h post-treatment (hpt) and an endpoint viability measurement at 36 hpt. Two phenotypes at alternate time points allowed us to sample drug dynamics, assess potential drug recovery, evaluate phenotypic discorrelation, and potentially reduce the number of false negatives. Z’-factors for motility and viability phenotypes were routinely greater than 0.7 and 0.35, respectively (Fig. 2e).

Identification and characterization of hit and target combinations with nanomolar potency against microfilariae. We used this optimized bivariate strategy to screen the Tocriscreen 2.0 library at 1 μM against B. malayi mf (Fig. 2f). The library contains 1280 bioactive compounds with pharmacological classes that have been theorized as anthelmintic targets, including GPCRs, kinases and other enzymes, ion channels, and nuclear receptors, among
The diversity of targets and their broad physiological roles increased the likelihood of obtaining hits associated with diverse phenotypes. While pursuing hit compounds with known activity in humans may enable drug repurposing, we are also interested in leveraging this information for the validation of parasite targets that could be diverted into mechanism-based screening strategies (Fig. 1a, b).

The primary screen identified 35 hits (Z-score >1; 2.7% hit rate) (Fig. 2g). While the overall correlation between the two phenotypes was high ($r = -0.84$), there was less correlation among our hits ($r = 0.33$), reflecting the capture of non-redundant phenotypic information. Indeed, only 32 (91%) or 11 (31%) hits would have been identified using only viability or motility alone, respectively. We presume that the later time point (36 hpt vs 12 hpt) of the viability assay is the primary reason for the greater number of hits, but also note that of the 11 motility hits, only eight were viability hits. Although these phenotypes often reinforce each other, they can also be decoupled by the action of particular drugs. The 35 hits span a range of target classes (Fig. 2h and Supplementary Data 2). Interestingly, four of the hits are histone demethylase inhibitors, and two act on the NF-$\kappa$B/I-$\kappa$B pathway. Out of the human targets, 16 contain homologs in $B$. malayi, 12 of them one-to-one, and the human targets of primary hits were not more likely to have more similar parasite homologs than the targets of non-hits (Supplementary Data 1, Supplementary Fig. 2).

We generated eight-point dose-response curves for 31 of these hits, recording motility at 12 hpt and both phenotypes at 36 hpt. Fifteen hits had a motility or viability phenotype at 36 hpt (>25% reduction in viability or motility when compared to control, Supplementary Fig. 3a). As expected, the liberal threshold set in the primary screen resulted in some compounds not reproducing an effect when retested. Six of eight compounds that produced effects in both motility and viability phenotypes in the primary...
screen reproduced effects in the dose-response experiment, while 2/3 and 7/19 of the motility and viability hits were reproduced, respectively. Thirteen of the hits had EC$_{50}$ values of <1 µM for at least one phenotype, and ten of these were <500 nM (Fig. 2i). Two hits had an EC$_{50}$ of less than 100 nM: NSC 319726, a p53 reactivator (19 nM) and NAV 2729, an Arf6 inhibitor (81 nM). These two compounds caused substantial motility and viability effects ($Z_{\text{Viability}} > 4.5$, $Z_{\text{Motility}} > 1.3$), suggesting that our primary screen had some predictive power for compound potency. Eleven of the top 15 hits from the primary screen were recapitulated with <1 µM EC$_{50}$ values, while only 3 of the bottom 22 hits produced a measurable EC$_{50}$ for any of the phenotype/time point...
Combinations. Indeed, there was a significant correlation between the EC50 for motility at 36 hpt and $Z_{\text{Viability}} + Z_{\text{Motility}}$ ($r = -0.594$, $p$ value $= 0.0249$, df = 12).

Dose-response experiments with measurements at multiple time points allowed us to distinguish between “fast-acting” compounds (Phenotype12 > Phenotype36) and “slow-acting” compounds (Phenotype12 < Phenotype36). We do not assume that a good anthelmintic lead compound (or target) should induce a fast effect. Slow deterioration of dead worms, leading to a slower release of antigens and commensal Wolbachia bacteria, may serve to reduce adverse effects after drug treatment10,18. Six compounds had effects at 12 hpt that were similar to the effects at 36 hpt (area between the curves <0.3) while the remainder had a higher effect at 36 hpt (Supplementary Fig. 3b). Two of the seven fast-acting compounds are NF-κB/IκB inhibitors.

Virtual screening has a modest ability to enrich for bioactive compounds and predicts orthologous targets with dissimilar binding pockets. Utilization of computational filters or surrogate screening models prior to a primary screen, with the goal of increasing throughput and efficiency, is a consistent theme in antifilial research and development. With data from our primary screen in hand, we investigated whether these alternative approaches could have identified the same hit compounds as those resulting from our primary screen, have allowed us to screen fewer compounds, or help direct towards the likely parasite targets of our hits.

We first tested the ability of virtual screening to recall known interactions. We docked each compound in the Tocriscreen library to a set of 3,284 AlphaFold2 (AF2) models of human proteins (4,194,311 total docking runs), which included the known target(s) of each compound. If this strategy could successfully extract known interactions, we could use it to generate leads for the parasite targets of hit compounds. We used AF2 models and blind docking in anticipation of translating the approach to the parasite, for which AF2 models exist but have unannotated binding sites. We tuned machine learning models to classify actives and decoys based on the known interactions with human targets. A tuned random forest achieved a 6-fold enrichment factor at 1% when evaluated on hold-out test data (that is, we were 6 times more likely than random to identify an active in the top 1% of probabilities generated by the classifier), a robust initial enhancement (RIE19) of 5.29, and a BEDROC20 of 0.14. These metrics indicate that our virtual screening strategy has a modest ability to recall compound-target interactions.

In addition, we tested whether this computational strategy could classify the hits that were identified in our bivariate, high-throughput phenotypic screen. We repeated the blind docking strategy with 828 parasite target structures—orthologs of the human targets used in the previous analysis—and used the tuned model to predict actives/decoys and predict the target for each hit compound (Supplementary Data 3). Our virtual screening strategy would have slightly enriched for actives, but any pre-filtration would have also led to a substantial dropout of hits (Fig. 3a). For instance, screening the 640 compounds that had the highest maximum docking probability (the best 50%) would have recovered 18 (53%) of the primary hits (Fig. 3a). Each compound’s maximum docking probability also had no correlation with the total Z-score from the primary screen (Supplementary Fig. 4).

Finally, the virtual screens allowed for comparison of the docking profiles of human and parasite orthologs as an assessment of binding pocket dissimilarities. Several approaches have been used to test the existence of a potential selectivity window when investigating anthelmintic protein targets with known host orthologs, including primary sequence similarity and structural alignment21–23. However, ortholog pairs can have low sequence identity while having highly conserved binding pockets, and structural alignment followed by assessment of binding pocket dissimilarity requires a priori target selection and knowledge of the binding site. We designed a metric that measured binding pocket structural dissimilarity between host/parasite orthologs using high-throughput blind docking (Fig. 3b). This metric ($M_3$) summarizes the deviation of site-specific docking affinities between orthologous pairs from the assumption that they would be identical for identical binding pockets. $M_3$ poorly correlates with other metrics of dissimilarity such as the root-mean-square deviation of atoms in aligned orthologous structures and the percent identity of aligned orthologous primary sequences, demonstrating that this metric provides unique information (Fig. 3b). Among putative targets of our primary screen hits, KDM5A/Bma-RBR-2 had the highest $M_3$, while ARF6/Bma—ARF-6 had the lowest (Fig. 3c, d). This metric leverages advances in deep learning for protein structural determination and molecular docking to generate genome-wide predictions of the ability to selectively target the parasite proteins where host orthologs can be identified.

C. elegans development poorly predicts antifilarial activity. The model nematode C. elegans has been used as a surrogate for anthelmintic screening efforts with mixed results, especially when used as a model for nematodes that reside in separate phylogenetic clades24,25. Nonetheless, C. elegans is a convenient screening model to discover nematocidal compounds and offers genetic tools that have enabled the discovery of the targets of such compounds26–30. To evaluate C. elegans as a primary screening model for antifilarial discovery, we assayed the effects of the Tocriscreen library on C. elegans development. Four compounds caused a development reduction one standard deviation away from the mean (0.3% hit rate), and only one hit (NAV 2729) was shared with the hits from the B. malayi mf primary screen (Fig. 4a). For this library, a C. elegans primary screening filter would have led to the discovery of only one of 35 compounds that have activity against B. malayi mf.

C. elegans has a thick collagen cuticle that is impermeable to polar and large molecules, and high concentrations of compound are often necessary to enable pharmacologically relevant bioaccumulation31,32. To test the possibility that the thicker cuticle of C. elegans masked the discovery of antifilarial compounds, we
exposed *C. elegans* to a higher concentration (10 µM) of the subset of compounds that were active against *B. malayi* mf. An additional 11 compounds caused significant developmental defects at 10 µM, but only two caused effect sizes >30% (ER 50891 and ML 228, Fig. 4b). These data clearly show that a *C. elegans* development screen provided little predictive power for identifying compounds with in vitro bioactivity against *filaria*, even when exposing worms to comparatively higher concentrations and longer exposure times.

*C. elegans* has been utilized as a platform for deconvoluting the target or mechanism of action of a hit shared between free-living and parasitic nematodes. We attempted to identify the target of drug-induced developmental delays. In the presence of drug, each knock-out strain experienced the same developmental delay as wild type, suggesting that these targets are not the primary mediators of the drug effect observed in *C. elegans* (Fig. 4c). ML 228 is believed to induce a hypoxia response in human cell lines by chelating iron, causing HIF-1α activation. The developmental effect of ML 228 on *C. elegans* persisted even in the *hif-1* knockout strain, suggesting that ML 228 does not activate a hypoxia response in nematodes.

We repeated *C. elegans* development assays with NAV 2729 or ML 228 treatment and hypoxia-inducible factor (HIF) activator. We repeated *C. elegans* development assays with NAV 2729 or ML 228 treatment and hypoxia-inducible factor (HIF) activator. We repeated...
therefore likely that both NAV 2729 and ML 228 exert their antinematodal activity through non-orthologous targets associated with different mechanisms of action to what is known in mammals.

Optimization of a multiplex adult screening regimen. *Brugia pahangi*, a parasite of felids that is closely related to the etiological agents of LF, can be reared in rodent hosts at higher yields than *B. malayi* and thus has been used as a surrogate in motility-based screens. To optimize a multiplex phenotyping strategy for macrofilaricides, we compared the activities of control and heat-killed *B. malayi* and *B. pahangi* during in vitro culture over a period of 5 days. Individual worms remain highly motile over this time period and produce measurable amounts of lactate (Fig. 5a, b). Female fecundity of both species showed a monotonic decrease over time, with *B. pahangi* being significantly more fecund than *B. malayi*, making it a more sensitive organism for measuring drug-induced inhibition (Fig. 5c, d). Females that started with low fecundity never increased in fecundity, allowing the formulation of a convenient filter for pretreatment health. Most females stopped laying mf after 48 h in culture, and heat-killed worms were incapable of laying progeny (Fig. 5e). These experiments also tested the effects of serum on worm health. Serum can have non-random effects on pharmacodynamics and can interfere with assays on conditioned media, making incomplete (i.e., serum-free) media the preference. Serum...
supplementation had no effect on motility over 5 days (Fig. 5a), but it did slow the decrease in fecundity (Fig. 5c).

Ex vivo filarial adults exhibit substantial phenotypic heterogeneity and batch variability. Female batches can vary in fecundity by three orders of magnitude (Supplementary Fig. 11), and both sexes display a complex variety of body postures and knotting behaviors. In order to control for this variation, we ensured that phenotypes could be self-normalized to a pretreatment value after overnight equilibration in complete media, followed by a 48 h assay timeline (Fig. 5f).

Identification of hit and target combinations with sub-micromolar activity against adult filarial parasites. Thirty-one of the hits from the primary screen were tested at 1 µM in this optimized secondary screen. Motility was measured before and immediately after drug addition, and at 1, 24, and 48 hpt. Fecundity was measured before drug addition and at the conclusion of the experiment. Metabolic activity was assessed via measurement of lactate produced in the conditioned media, and worms were terminally stained with CellTox to measure potential adulticidal activity of the compounds.

We defined a motility hit as any compound that causes >50% decrease in motility in over half of the tested worms, or an average decrease of 75%; similar cutoffs were used for the other phenotypes (see Methods). This heuristic ensured that a single worm that showed a stochastic increase in motility did not cause false negatives when the other worms all exhibited substantial decreases in motility. Thirteen compounds satisfied this threshold after 48 h, a hit rate of 32% (Fig. 6a, b). Four of these compounds caused motility reductions in both sexes, 3 in females only, and 6 in males only. The motility hits against females only accounted...
Fig. 6 Secondary screen of adult male and female *B. pahangi*. a Motility of worms after 48 h post-treatment (hpt). Compounds in light blue are hits, navy blue are not hits. b Individual worm motility over time. Ø = immediately prior to drug addition, 0 = immediately after drug addition. c Progeny released 48 hpt. (Inset) Female worms that released <200 mf after overnight culture in complete media were filtered from downstream analysis. d Lactate production after 48 hpt. e Example images of viability-stained adults. Stained worms are dead. Scale bars represent 500 µm. For all bar charts, each point is an individual worm, columns are the mean of the group, and bars represent the standard error of the mean.
for 6 of the 11 compounds that were most effective in causing a reduction in fecundity (Fig. 6c). That is, 5 compounds had a fecundity effect on females but did not have a motility effect. Eight compounds caused reductions in lactate release by females, and 4 caused reductions in males (Fig. 6d). In females, all the motility hits were also metabolism hits, two hits were only metabolism and fecundity, and one was a metabolism only hit. In males, two hits were metabolism hits but not motility hits, seven hits were motility only hits, and two were hits in both phenotypes (Fig. 7a). In total, 17 compounds (55%) elicited a hit in at least one phenotypic assay, with female fecundity being the most sensitive phenotype (11 hits). These data clearly show that the additional multiplexed phenotypes reveal information about compounds that would not have been captured using motility alone.

Two compounds (Ciclopirox and GSK J4) had effects across all five phenotypes, and ML 228 had an effect on four phenotypes (Fig. 7a). Ciclopirox and GSK J4 are histone demethylase inhibitors (KDMIs), and a third KDMI (JIB 04) had a female-specific effect. KDMIs have a rich history as antischistosomal leads36–38, and have been recently identified in macrolaricidal screening regimens39. Our data add to this corpus of evidence, and, interestingly, our two-stage screening approach suggests that these epigenetic drugs may be potentially effective as specific adulticidal targets. All four of the KDMIs that were identified in the primary screen poorly reproduced in dose-response experiments, adding to the evidence that although they have effects against mf, they are much more potent against adults39.

Furthermore, GSK J4 and ML 228 are likely adulticidal, as some treated worms were brightly stained by a cytotoxicity stain (Fig. 6c).

We collated the data from all the parasite screens and clustered the hits based on scaled phenotypic values (Fig. 7b). Hits were classified into four broad categories: (1) those with high EC₅₀ values on mf and no effects on adults (14 compounds), which clustered with DMSO; (2) those with high EC₅₀ values on mf and potent effects on adults (5 compounds, macrolaricidal), which clustered with ivermectin; (3) those with low EC₅₀ values on mf and no effects on adults (4 compounds, microfilaricidal); (4) those that were potent against both mf and adults (9 compounds).

A summary of all screening data can be found in Supplementary Data 2. The most interesting compounds characterized by this thorough set of analyses include the aforementioned ARF6 inhibitor, which is lethal to mf, has an EC₅₀ on motility of 81 nM, decreases C. elegans length by more than 50% at 5 μM, and reduced male motility by 75% at only 1 μM; the four histone demethylase inhibitors, which have parasite-specific effects and greatly reduce female fecundity; the two NF-κB/IκB inhibitors, which have highly potent effects on motility but reduced effects on adults, and ML 228, which is more potent on adults than mf and caused significant effects on several adult phenotypes. However, one of the unique strengths of our approach is the ability to illuminate diverse bioactivities of different hit compounds, allowing investigators to prioritize compounds associated with diverse mechanisms linked to different emergent phenotypes of relevance to in vivo efficacy.

**Discussion**

The development of macrofilaricides is a key component to eliminating filarial neglected tropical diseases and was recently recognized as a critical action in the World Health Organization’s 2021–2030 roadmap40. The movement to utilize in vitro screening of parasites as the primary driver for macrofilaricide development has yielded few leads even with massive investment. Targeting the endosymbiont Wolbachia to sterilize and slowly kill adult worms is an alternative strategy, and doxycycline has been successfully used in a test-and-treat approach for onchocerciasis41. High-throughput screening has recently identified a number of anti-Wolbachia leads that exhibit desirable preclinical traits, some of which are now in clinical trials42–45. However, compounds that act directly on parasites are still highly desirable, even if leveraging high-throughput technologies to identify them are hindered. Repurposing anthelmintics from veterinary medicine for the treatment of filariases is an additional ongoing effort, and emodepside is currently advancing through clinical trials for the treatment of onchocerciasis, but is not viable as a treatment for LF46.

We developed and deployed a strategy to identify direct-acting macrofilaricides, incorporating a highly optimized primary screen against microfilaria to enrich for compounds with antifilarial activity. Primary hits were then characterized for activity against adults by inspecting an expanded repertoire of multiplexed disease-relevant phenotypes, in contrast to traditional single-endpoint screens. This tiered approach greatly reduced the time and investment required for hit identification and substantially increased the amount of information gleaned about a compound of interest. Even though the primary screen was carried out against mf, it resulted in the identification of compounds with greater potency against adults than mf, which is a desirable property in regions where rapid mf death may result in severe adverse events3. Likewise, utilizing multiple time points in the primary and secondary screens allowed us to prioritize drugs based on the preference for slow or fast-acting compounds and/or compounds that cause permanent or transient, and therefore potentially recoverable, effects.

Chemogenomic approaches in which compounds are used as molecular probes linked to known host targets provide leads for parasite target identification and have been used to great effect in other infectious disease systems, including Plasmodium falciparum and Mycobacterium tuberculosis47,48. Given the phylogenetic distance between the host, in which the compound-target pairs were characterized, and the parasite, target deconvolution in the parasite is essential. In contrast to P. falciparum and M. tuberculosis, the genetic tools used to discover and validate targets are under-developed in filarial parasites. Use of the genetically tractable model nematode C. elegans allowed us to rule out the predicted targets of two drugs with conserved activity across filarial and free-living nematodes. Although we had anticipated mapping drug effects to host-orthologous targets, our results reveal a more desirable trait: compounds with potent antifilarial activity that are most likely mediated by completely novel mechanisms. For example, NAV 2729 was highly potent against mf and had strong male-specific effects on adults; but these actions are not mediated by the nematode homolog of the known human target (ARF6). The same is true of ML 228, a compound that had strong effects against both adult sexes within 24 h and was comparatively less potent against mf, but for which the HIF homolog is not the nematode target.

For the antifilarial compounds that also cause developmental delay in C. elegans, forward genetic screens can be utilized to identify the nematode target instead of a candidate gene approach. Mapping the targets of compounds with specific antiparasitic action, such as the multiple mammalian KDM and NF-κB pathway inhibitors, will require a different approach. Reverse genetics approaches have been used to validate anthelmintic targets23,49,50, as have candidate gene approaches based on the known interactions between the compound and host targets51. These could be similarly leveraged to elucidate targets of our hit compounds, though an RNAi-based strategy would only be available for adult hits and would be highly target-dependent. Virtual screening of structural models inferred by deep-learning had limited utility in target identification, but it
Fig. 7 Antifilarial hits cluster into four phenotypic groups. a Tally of the number of hits from each assay combination. For instance, two compounds were hits in all five assays, and four compounds were hits in the male motility assay alone. b Hits against microfilaria (mf) in the primary screen but failed to reproduce in the follow-up dose-response and had no effects against adults (black rectangle) clustered with the negative control (yellow highlight). Four compounds were potent against mf but had no effect on adults, five compounds were relatively less potent against mf but had strong effects on adults, and the remaining hits (nine compounds) were potent against mf and adults (blue boxes). For the top panel, fill color represents the scaled Euclidean distance between compounds using every available phenotypic value. Distances were scaled between −1 and 1 and compounds were clustered using Ward’s method. For the bottom panel, fill color represents the scaled inhibition such that the compound that caused the greatest effect in a given phenotype is given a value of 1.
provided a method of assessing structural dissimilarity between host and parasite orthologs. Off-target host toxicity is an ever present concern when dealing with multicellular eukaryotic parasites, and outside of traditional medicinal chemistry and comprehensive structure-activity relationship studies, which require heterologous expression of the target and a relevant high-throughput screening assay, few approaches have been developed to assess genome-wide structural dissimilarity between host-parasite orthologs. Methods based on primary sequence similarity have proliferated in tandem with the assembly of new helminth genomes, but the pharmacological relevance of these approaches remains unclear. In contrast, our approach using high-throughput molecular docking generates affinity profiles for each potential binding pocket and allows for the unbiased, genome-wide determination of targets with the most dissimilar docking profiles. This approach provides unique information that can be incorporated when evaluating and selecting drug targets from genomic data sources.

We present here a comprehensive optimization of phenotypic and computational screening strategies for antifilarial drug and target discovery. We identified conserved activity among species, and/or sex-specific activity, some with submicromolar potency. The phenotypic spectrum of each hit compound is thoroughly profiled through the use of parallelized multivariate assays, providing a rich dataset that allows the selection of compounds with distinct traits rather than characterizing a compound simply as an "active." Each compound is linked to a putative target, and the use of model organisms and virtual screening of structural models provides leads for target identification. Prioritized compounds are now poised for testing in animal models of infection as well as in vitro characterization against other filarial nematodes. The public availability of the library as well as the profiling against human known targets should make these tests relatively straightforward. Finally, these data also seed future compound and target-centric investigation of diverse hit profiles, and the methods developed provide an advanced strategy for filarial phenotypic screens and antifilarial discovery.

Methods

Parasite maintenance. Brugia malayi and Brugia pahangi life cycle stages were obtained through the NIH/NIAID Filariasis Research Reagent Resource Center (FR3); morphological voucher specimens are stored at the Harold W. Manter Museum at University of Nebraska, accession numbers P2021–2032 and P2031. Parasites were maintained at 27°C with 5% atmospheric CO2 in RPMI 1640 culture media (Sigma-Aldrich, St. Louis, MO) with penicillin/streptomycin (0.1 mg/ml, Gibco, Gaithersburg, MD) and FBS (10% v/v, Gibco) unless otherwise stated.

Screening of Brugia malayi microfilariae. A chemogenomic compound library of 1280 bioactive small molecules (Tocriscreen 2.0, Tocris Bioscience, Minneapolis, MN) was stored at 1 mM in DMSO in low dense volume 384-well plates. Assay-ready plates were generated at the UW-Madison Small Molecule Screening Facility with a Labcyte Echo 650 (Beckman Coulter, Brea, CA) liquid handler by spotting each compound onto 96-well assay plates (Greiner Bio-One, Frickenhausen, Germany), which were sealed with adhesive foil, wrapped in parafilm, and stored at −20°C. The entire library was screened against B. malayi microfilariae (mf) at 100 and 1 µM after a single freeze–thaw cycle. A detailed procedure for performing the primary mf screen is reported at: https://doi.org/10.21203/rs.3.pex-1916/v2. Videos were analyzed with the motility and segmentation modules of wrmXpress v1.3.0.54. Videos were analyzed on a node maintained at UW-Madison’s Center for High Throughput Computing (CHTC). Output data were analyzed using the R statistical software, including tidyverse packages and drc to analyze dose–response experiments.59,60. Motility data was processed by normalizing flow values to the log, of the segmented worm area, corrected using a linear model that included well row and column as numeric predictors, and scaling between 0 and 1 using the means for the negative (1% DMSO) and positive (heat-killed) controls, respectively. Outliers (identified using the IQR method with a coefficient of 3) in positive and negative controls were removed. Hits were defined as any treatment that had a Z > 1.

Screening of C. elegans. C. elegans N2 (Bristol) were maintained at 20°C on NGM plates seeded with E. coli OP50 and routinely picked to fresh plates at the L4 stage. Gravid worms were bleached and embryos were hatched in K media (or S media for iron chelation experiments) overnight (14–20 h) at a concentration of 3 × 10^5/ml. Hatched L1s were titrated by counting 10 aliquots of 5 ml spots, and K or S media was added to adjust the suspension to 1 L1/ul. Food solution was made by diluting frozen E. coli HB101 stock (50 mg/ml) 10X in K or S supplemented with kanamycin (Fisher Scientific AC568100100, Waltham, MA).

For the 1 µM library screen, assay-ready plates were prepared with 1000X compound, and the first/last control plate contained final concentrations of 1% DMSO or 50 µM albendazole sulfoxide (Fisher Scientific). In all, 50 µl of the titrated L1 culture was added to each well followed by 50 µl of food solution. Plates were sealed by a sterile film and incubated at 20°C in a humid chamber with shaking at 180 RPM. At 48 hpt, each well was filled with sodium azide (final concentration 50 mM, Fisher Scientific) or 1-phenoxyl-2-propanol (1PP2, Sigma-Aldrich, final concentration 0.7%) to paralyze the worms, and entire wells were imaged at 2X with an ImageXpress Nano (Molecular Devices).

Images were analyzed with the worm size module of wrmXpress.54. Segmented worms were computationally straightened, and the length of each worm was used to measure development.

Multivariate screening of adult Brugia pahangi. A detailed procedure for performing the multivariate adult screen is reported at https://doi.org/10.21203/rs.3.pex-1918/v2. Adult B. pahangi were extracted from Mongolian jirds 377 days post-infection. Care was taken to work quickly and keep parasites at physiological temperature, as we have observed substantial differences in worm behavior when exposed to room temperature. Adult worms were washed with saline against both sexes, and plates were recorded in a custom imaging setup prior to adding drug, immediately after adding drug, and 1, 24, and 48 hpt (Fig. 3A). At 48 hpt, worms were picked from 24-well plates to 96-well plates with 100 µl of PBS per well and stained for viability.

Adult Brugia pahangi motility analysis. Videos of individual worms were cropped and motility was measured with a previously described optical flow algorithm.68. For optimization experiments, worms with 0 h flow values of <5% of the minimum value or less than the background flow were annotated as dead and removed from any further analysis, as were any flow value that was >2.5x that worm’s 0 h flow value. For screening experiments, the raw optical flow was log10 transformed, and the background flow was subtracted using the mean flow of empty wells. Videos were also manually inspected and nonmoving worms at the 0 h time point were removed from further analysis. A hit was defined as any compound that caused a decrease of >50% in motility in over half of the tested worms, or a group average decrease of >75%.

Adult Brugia pahangi fecundity analysis. B. pahangi females lay a mix of embryos, prestage stage mf, and mature mf in vitro. We designed a computer imaging algorithm to count images of progeny in a high-throughput manner. First, progeny from images of 250 wells were manually counted. Next, we used Fiji to segment worms using a Sobel filter, Gaussian blur (σ = 2.5), and the default iterative selection method for thresholding, and segmented pixels were counted. We split these data into truth and training datasets and used tenfold cross validation to fit and evaluate a linear model, which explained 88% of the variation in pixel coverage (Supplementary Fig. 12). This model was used to analyze all subsequent wells. Each fecundity value from 48 hpt was normalized to the pretreatment time point to generate a measure of relative fecundity. Parasites that released less than 200 progeny during the overnight recovery period were removed from further analysis. A hit was defined as any compound that caused a decrease of >50% in fecundity in more than two worms, or a group average decrease of >50%.

Adult Brugia pahangi viability analyses. Adult parasites picked into PBS in 96-well plates were stained with CellTox (Promega, Madison, WI) using the manufacturer’s protocol, except using 1/2 the recommended concentration of reagent. Adult parasites were washed twice with PBS, washed with PBS, and stained with PBS and green fluorescence was imaged at 2X with an ImageXpress Nano. A 14-slice Z-stack was imaged with 250 µm separating each slice, and a maximum projection of the stack was used to assess fluorescence. Worms were segmented with a Sobel filter and Gaussian blur (σ = 10), thresholded as above, eroded (×3), and the area of particles with ellipticity of 0–0.5 was measured.

Adult Brugia pahangi metabolic analysis. Conditioned media was thawed and filtered through a 0.2 µm filter plate (Pall, Port Washington, NY) by centrifuging at 1500 × g for 2 min, and filtered media was diluted in PBS to a final dilution of 1:50 for males and 1:150 for females. Lactate production was quantified using the Lactate-Glo kit (Promega), following the manufacturer’s protocol. Luminescence was measured with a SpectraMax 13x plate reader (Molecular Devices). A hit was defined as any compound that caused at least 50% decrease in luminescence in more than two worms, or a group average decrease of >25%.

Comparative genomics and phylogenetics. Parasite homologs of the human targets of hits in the primary screen were identified with a comparative genomics
pipeline. The list of human targets was first expanded using a BLASTp search against the human predicted proteome and retaining hits with percent identity >30%, E-value <10⁻³, and p-value coverage >40%. This expanded list was used for a BLASTp against the predicted proteomes of B. malayi, Anclostoma canum, Ascaris suum, C. elegans, Haemonchus contortus, Strongyloides ratti, and Trichuris muris (all predicted proteomes were downloaded from WormBase ParaSite v1660). Hits were filtered as above. Surviving hits were used in a reciprocal BLASTp against the human predicted proteome. Parasite homologs that had top hits to the respective human targets were maintained. Target homologs were aligned, trimmed, and phylogenetic trees were inferred with IQ-TREE. Trees were visualized and annotated with ggtree. The entire pipeline can be found at https://github.com/zamanianlab/Phylogenetics/tree/master/Tocris and trees are in Supplementary Data 1.

Virtual screening against human and parasite AlphaFold2 protein structures. A blind docking procedure was used to predict compound-target binding poses and interaction scores for compounds in the Tocriscreen 2.0 Mini chemical library with AlphaFold2 protein structure models for human and available B. malayi orthologs. Scoring features generated from docked compound-target pairs pro-vided input representations for machine learning classifiers. Scripts containing the full commands and all analytical code can be found at https://github.com/zamanianlab/MultivariateScreening.ms.

The compound library was obtained from Tocris in SMILES format along with catalog IDs and UniProt annotations of the known human protein targets. In all, 1280 SMILES were downloaded with unique catalog IDs and were sanitized using RDKit (RDKit: Open-source chemoinformatics. https://www.rdkit.org) to produce 1278 RDKit-canonical, isomeric SMILES (Supplementary Data 4). Protonation states were set using fixpka utility from OpenEye Scientific, Inc. (QUACPARC 2.2.0.1, 2021). For blind docking, more extensive sampling is required (exhaustiveness = 64, rather than default value of 8). The target protein structure was specified as the argument for the autobox ligand option to enable blind docking. CNN scoring was used only for re-scoring final poses by setting cnn_scoring option to ‘rescore’. For CNN-based pose scoring, the “cnn_layout2018” model was selected. The top scoring pose based on CNNscore was selected to represent each compound-target pair. All docking runs were performed at the CHTC, which manages job access to Open Science Grid compute resources.68 Pose locations were calculated as geometric centroid points and stored for docking site analysis on each target class. Points in each target class were classified by DBSCAN69 with $\varepsilon = 1.5$ Å and the $min\_samples$ threshold scaled for each target class as $sqr(N)/2$, where $N$ is the total number of poses (points). Based on pose cluster assignments, an additional scoring feature, site consensus score, was computed for each pose as the fractional occupancy of its pose cluster with respect to all poses observed in target class. For example, if 10% of all poses in a given target class were observed in a given pose cluster, poses in this cluster were assigned a site consensus score of 0.1. Outlier poses were then assigned a site consensus score of 0.0. Random forest and XGBoost70 machine learning models were tuned and fit to the human target docking data using true compound-target pairs. Parameters were tuned using tenfold cross-validation and evaluated on hold-out test data. The data set (~1800 actives and ~3.5 m decoys) was balanced by downsampling. Models were evaluated using a variety of metrics, including the enrichment factor at 1% (EF1), BEDROC,69 and RIE,19 which were implemented into the tidymodels framework using a custom package (https://github.com/zamanianlab/ZamanianLabVSTools). Statsitics and reproducibility. For high-throughput screens, hits were identified as those compounds that had a Z-score >1 ($Z = (x - \mu)/\sigma$). The $Z$-factor$44$ of the plate was calculated using the equation: $Z = 1 - 3\sigma (\bar{z} + 0.5)$. Correlation between raw and subsampled mF videos was assessed using Spearman’s correlation coefficient. Screens against B. malayi mf and C. elegans N2 were completed once. For B. malayi mf dose–response experiments, 4 technical replicates (wells) were included for each concentration, and dose–response curves were fit to a four-parameter log-logistic curve. For C. elegans development assays, Dunn’s test for nonparametric multiple pairwise comparisons was used to compare treatment groups to the negative control. For $p$ values, all multivariate experiments, four worms were used for each sex, all coming from a single batch extracted from jirds that were infected on the same day with the same batch of L3s. Comparisons of fecundity between Brugia species was calculated using a Kruskal–Wallis one-way analysis of variance. A measure of binding pocket dissimilarity ($M_d$) was calculated using the equation: $M_d = \frac{2}{\mu + \sigma} + \frac{2}{\sigma + \mu}$, where $\mu$ is a CNN output and $\sigma$ is the compound docked.

Reporting summary. Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

All data used to produce figures are available as RDS files https://github.com/zamanianlab/MultivariateScreening.ms. An archived release of this repository can be found at https://doi.org/10.5281/zenodo.7455781. All raw imaging data (>2 TB) is available upon reasonable request. Docking results and tuned machine learning models are available in a Zenodo repository (https://doi.org/10.5281/zenodo.5999609).

Code availability

All analyses and figures can be reproduced using the code found at https://github.com/zamanianlab/MultivariateScreening.ms. An archived release of this repository can be found at https://doi.org/10.5281/zenodo.7455781. vrnXpress v1.3.0 was used for image analysis.
