The momentum dependent $K^-$-nucleus optical potentials are obtained based on the relativistic mean-field theory. By considering the quarks coordinates of $K^-$ meson, we introduced a momentum-dependent “form factor” to modify the coupling vertexes. The parameters in the form factors are determined by fitting the experimental $K^-$-nucleus scattering data. It is found that the real part of the optical potentials decrease with increasing $K^-$ momenta, however the imaginary potentials increase at first with increasing momenta up to $P_k = 450 \sim 550$ MeV and then decrease. By comparing the calculated $K^-$ mean free paths with those from $K^- n/K^- p$ scattering data, we suggested that the real potential depth is $V_0 \sim 80$ MeV, and the imaginary potential parameter is $W_0 \sim 65$ MeV.

Recently kaon nuclear physics has been a hot topic of nuclear physics, and kaon-nucleus interaction is a key point to many studies on kaon. The information of $K^-$-nucleus interaction were obtained from $K^-$- atomic and $K^- N$ scattering data. Since kaon is only sensitive to the surface structure of nuclei in $K^-$- atomic, predictions on $K^-$-nucleus interactions are very different for different models (a very strong attractive real potential, $150 \sim 200$ MeV, from the density dependent optical potential (DD) model $^1$; and a much shallower one $\sim 50$ MeV from the chiral model $^3$). On the other hand, Sibirtsev et al. predicted the kaon-nucleus interaction has “momentum dependence” from $K^- N$ scattering data $^4$. They have obtained a momentum dependent potential in a dispersion approach at normal nuclear density, the potential depth is about $140 \pm 20$MeV at zero momentum, and decreases rapidly for higher momenta. In our previous work $^5$, we also found that the kaon nucleus optical potential has strong momentum dependence by fitting the only experimental data on the $K^- C$, $K^- Ca$ scattering at $P_k = 800$ MeV/c $^6$. We indicated that the depth of real potential at the inner nuclei is $(45 \pm 5)$ MeV at $P_k = 800$ MeV/c, which is much shallower than that at zero momentum in the RMF. We shall here be concerned with discussing

the momentum dependence of $K^-$-nucleus interaction within the framework of RMF.

In the usual RMF model, one cannot obtain the correct momentum dependence of $K^-$-nucleus interaction, and have to take the internal structure of kaon into account to introduce a momentum-dependent “form factor” [7]. When RMF is extended to study KN interaction at the quark level, the same approximation as made in the quark-meson coupling (QMC) model [8, 9] should be introduced: $\sigma$- and $\omega$-mesons are exchanged only between the $u, d$ quarks or their anti-quarks in $K$ meson, contributions from the $s$ quark are ignored. In the following, we shall take kaon as a two quarks system to introduce an exponential “form factor”, $\exp(-P_k^2/4\kappa^2)$, which modify the couplings vertexes. In fact, similar exponential “form factor” has been widely adopted to improve various calculations [10, 11, 12].

![Feynman diagram for the KN interactions and internal coordinate of two quark system](image)

FIG. 1: Feynman diagram for the KN interactions and internal coordinate of two quark system

In the RMF, the $KN$ interactions are described by exchanging scalar meson $\sigma$ and vector meson $\omega$ [13]. At the quark level, $\sigma$- and $\omega$-mesons are exchanged between the $u, d$ quarks or their anti-quarks. See Fig. 1, the scalar and vector couplings are

$$
\mathcal{L}_\sigma = g_{\sigma K} m_K \bar{K} \sigma K,
$$

(1)

$$
\mathcal{L}_\omega = i g_{\omega K} \bar{K} \omega^\mu \partial_\mu K + H.C.
$$

(2)

Replacing the scalar meson $\sigma$ and vector meson $\omega$ with their plane wave form to get,

$$
\mathcal{L}_\sigma = g_{\sigma K} m_K \bar{K} \left( a_\sigma e^{-iq \cdot r_2} \right) K,
$$

(3)

$$
\mathcal{L}_\omega = i g_{\omega K} \bar{K} \left( a_\omega e^{-iq \cdot r_2 \varepsilon^\mu} \right) \partial_\mu K + H.C.,
$$

(4)

where $r_2$ represents the coordinates of $u/d$ quarks, with respect to the center of mass coordinates $\mathbf{R}$ and the relative coordinates $\mathbf{r}$ in the quark model. And we assume $q = cP_k$ approximately as the transferred momentum being proportional to $K^-$ incidence momentum. Thus one get

$$
e^{-i\mathbf{q} \cdot \mathbf{r}_2} = e^{-ic\mathbf{P}_k \cdot \mathbf{R} + \frac{q^2}{2}c^2 \mathbf{P}_k \cdot \mathbf{r}}.
$$

(5)
On the harmonic-oscillator basis, if the relative coordinates $r$ is rewritten in the second-quantized form, then

$$e^{-i\mathbf{q} \cdot \mathbf{r}} = e^{-i\mathbf{P}_K \cdot \mathbf{R}} e^{\frac{e^2p^2}{\hbar^2}} e^{\frac{i\mathbf{P}_K \cdot \mathbf{a}}{m_2}} e^{\frac{i\mathbf{P}_K \cdot \mathbf{a}^\dagger}{m_2}}.$$

(6)

Finally, approximately we have

$$L_\sigma \simeq g_\sigma K m_K F(P_k^2) \bar{K} K a_\sigma e^{-i\mathbf{P}_K \cdot \mathbf{R}},$$

(7)

$$L_\omega \simeq i g_\omega K F(P_k^2) \bar{K} \varepsilon^\mu a_\omega e^{-i\mathbf{P}_K \cdot \mathbf{R}} \partial_\mu K + H.C.,$$

(8)

with

$$F(P_k^2) \equiv \exp[-P_k^2/(4\kappa^2)],$$

(9)

where $\kappa^2 \equiv \alpha^2(m_u/c\mu)^2$, and $P_k = |\mathbf{P}_K|$.

In the c.m. system of $K$-meson, replace $a_\sigma e^{-i\mathbf{P}_K \cdot \mathbf{R}}$ ($a_\omega \varepsilon^\mu e^{-i\mathbf{P}_K \cdot \mathbf{R}}$) with $\sigma$ ($\omega^\mu$), Eqs. (7, 8) can be rewritten as,

$$L_\sigma \simeq g_\sigma K m_K F(P_k^2) \bar{K} K \sigma,$$

(10)

$$L_\omega \simeq i g_\omega K F(P_k^2) \left[\bar{K} \partial_\mu K - K \partial_\mu \bar{K}\right] \omega^\mu.$$

(11)

Comparing with the formulation without considering the quarks coordinates of $K$-meson, it is obvious that an additional factor $F(P_k^2)$ appears in the vertexes. Thus, the usual RMF Lagrangian for $KN$ interaction should be modified as

$$L_K = \partial_\mu \bar{K} \partial^\mu K - m_K^2 \bar{K} K - g_\sigma K m_K F(P_k^2) \bar{K} K \sigma$$

$$-i g_\omega K F(P_k^2) \left[\bar{K} \partial_\mu K - K \partial_\mu \bar{K}\right] \omega^\mu$$

$$+ \left[g_\omega K F(P_k^2) \omega^\mu\right]^2 \bar{K} K.$$

(12)

After a few simply deductions [13], we can obtain the real part of the $K$-nucleus optical potential,

$$\text{Re}U = \left[g_\sigma K m_K \sigma_0 - 2 g_\omega K E_K \omega_0 - F(P_k^2)(g_\omega K \omega_0)^2\right] \cdot F(P_k^2)/2m_K,$$

(13)

which refer to the $K$-meson three momenta by the form factor $F(P_k^2)$. The $K^-$-meson energy $E_K$ can also be deduced from the RMF model [13],

$$E_K = \sqrt{m_K^2 + g_\sigma K F(P_k^2)m_K \sigma_0 + F_k^2 - g_\omega K F(P_k^2) \omega_0}.$$
Here the coupling constants $g_{\pi K} = 2.088$ and $g_{\omega K} = 3.02$, which are used mostly in the RMF \[13\].

Up to now the anti-kaon absorption in the nuclear medium are ignored, since imaginary potential cannot be obtained directly from RMF. Similar to our previous work \[13\], we assumed a specific form of the imaginary potentials:

$$\text{Im}U = -f \cdot [F_2(P_k^2)]^2 \cdot \left[ \frac{E_K W_0}{m_k \rho_0} \right],$$

(15)

where $F_2(P_k^2) = e^{-P_k^2/(4\beta^2)}$, which is also introduced to modify the imaginary potential (i.e. decay widths) as did in the real part. For the decay width $\Gamma \propto M^2 \propto g^2$, where $M$ is the decay amplitude, and $g$ is the coupling, the square of the “form factor” $[F_2(P_k^2)]^2$ is adopted. Besides, the phase space available for the decay products should be considered \[13, 15\], which effects the imaginary potentials (widths). Thus, a factor, $f$, multiplying imaginary potentials $\text{Im}U$ is introduced in our calculations, as did in Ref. \[13\] (replace Re$E$ with $E_K$ of Eq. (14)). The factor $f$ can be assumed a mixture of 80% mesonic decay and 20% non-mesonic decay \[14, 15\], thus $f = 0.8f_1 + 0.2f_2$.

The imaginary potential parameter $W_0$, which is the depth of the imaginary potential at zero momentum, is not determined well. By fitting the $K^-$ atomic data, $W_0 \sim 50$ MeV \[1, 2\], however, the predictions in Refs. \[16, 17\] give a much deep value $W_0 \sim 100$ MeV. In this work, we shall discuss several cases for $W_0 = 50, 65, 80$ MeV.

![Image](image_url)

**FIG. 2:** On the several cases of different real (c, d) and imaginary (a, b) potentials, the elastic differential cross section for $K^-$ scattering from $^{40}Ca$ and $^{12}C$ as functions of c. m. angles at $p_k = 800$ MeV/c are shown in Figs. (a, c) and (b, d), respectively. The experimental data are from Ref. \[8\].

Finally, a momentum-dependent $K^-$-nuclear potential is obtained. Naturally, we do not expect the naive quark model to give appropriate values for the parameter $c$ and $\beta$. In the calculation, the
FIG. 3: The real and imaginary anti-kaon optical potentials in normal nuclear matter based on our model (solid dotted lines) and the other models are shown in Fig.(a) and (b), respectively. The solid pentagons curves are the predictions of a meson-exchange model with the Jülich $KN$ interaction [18]. The hollow pentagons curves are the results based on the lowest-order meson-baryon chiral lagrangian (the anti-kaons and pions are dressed self-consistently) [19]. The shadow region between two solid curves is the results predicted by Sibirtsev and Cassing (SC model) [4], and the crossed rectangle indicate the results from the analysis of $K^-$ production in $Ni + Ni$ collisions [20, 21].

parameters $\kappa$ and $\beta$ are determined by fitting the $K$-nucleus scattering data. The experimental data of the differential elastic cross sections for $K^- 12C$ and $K^- 40Ca$ at $P_K = 800$ MeV/c [6] are used to determine the parameters $\kappa = 0.275$ GeV and $\beta = (0.49, 0.44, 0.42)$ GeV (corresponding to $W_0 = 50, 65, 80$ MeV, respectively). In Fig. 2(a, b), according to the optical potentials from equations (13) and (15), the experimental data are fitted very well. With the determined parameters, we plotted the potentials as functions of kaon three momentum $P_k$ at normal nuclear density in Fig. 3. The real and imaginary parts are shown in Fig. 3(a) and (b), respectively. The solid dotted lines are our calculations of Eqs. (13, 15), the potentials predicted by the others [4, 18, 19] are also presented in the same figure.

From Fig. 3(a), we can see that our results on real potentials decrease with increasing momenta, their varying tendencies are in agreement with the other models [4, 18, 19]. The depths predicted by us are deeper than those of chiral and Jülich models. Among these models, chiral model gives much shallower real potential depths than the other three models. The results of Jülich $KN$ interaction and RMF model (with form factors) are compatible at $P_K < 600$ MeV, which are almost in the
possible region predicted by SC model. On the other hand, the real potential based on the RMF without “form factor” is also shown in Fig. 3(a). It is obvious that $F_1(P_K^2)$ has a great influence on the real potential, its corrections to the varying tendency of the real potentials are important. From Fig. 3(b), our results of the imaginary potentials increase at first with increasing momenta up to $P_k = 450 \sim 550$ MeV and then decrease, their varying tendencies are in a similar way to the results of Ref. [18]. There is a flat for imaginary potential curve in the low energy $P_k < 100$ MeV region, which is referred to the factor $f_1 = 0$, indicates that the total energy ($M_N + E_K$) is less than the threshold of $\Sigma\pi$, and the decay channel $NK \rightarrow \Sigma\pi$ is closed.

![Graphs showing mean free paths and potentials](image)

**FIG. 4:** According to the different imaginary (real) potentials, the $K^-$ mean free paths as functions of the incident momenta in normal nuclear matter are shown in Fig.(a)(Fig.(b)). The mean free path from the experimental $KP$ and ($KP + Kn)/2$ total cross sections are also presented. Corresponding to the $\lambda_{K^+}$ in Fig.(b), the real and imaginary parts of $K^-$ optical potentials are also shown in Fig.(c). However, $K^-$-nucleus elastic scattering data are not good enough to test the validity of the physics contained in our model. Since little experimental information came directly from the inner nuclei for kaon, there are much uncertainties in both the real potentials and the imaginary parts. The $K^-$ mean free paths (MFP) in nuclear matter can be calculated with the determined
momentum-dependent potentials, which can also be estimated from the experimental data of the total cross sections for $K^{-}p$ and $K^{-}n$ \[22\]. By comparing the results in two different approaches, we expect to find more constraints on the $KN$ interactions.

The details of how to calculate a particle’s MFP are given in our previous work \[23\], only the formula of $\lambda_K$ is given here,

\[\lambda_K = \frac{1}{2\sqrt{m_K \cdot [B^2 + (\text{Im}U)^2]^{\frac{1}{2}}} - m_K \cdot B}, \quad (16)\]

where, $B \equiv E_K - m_K - \text{Re}U + (E_K - m_K)^2/2m_K$. On the other hand, the MFP of $K^-$ is related to the $K^-p/K^-n$ scattering data by a simple relation $\lambda = 1/\rho\bar{\sigma}$, where $\bar{\sigma} = (\sigma_Kn + \sigma_Kp)/2$ is the average of total $K^-n$ and $K^-p$ cross sections. There are some $K^-p$ scattering data in the range of $240 < P_K < 1000$ MeV, and a few data for $K^-n$ scattering in $600 < P_K < 1000$ MeV. Thus only the MFP data from $\bar{\sigma} = (\sigma_Kn + \sigma_Kp)/2$ in the latter region can be compared. The results of two approaches are shown in Fig. 4.

From the figure, we find that $\lambda_p (= 1/\rho\sigma_{Kp})$ is a little larger than $\lambda (= 1/\rho\bar{\sigma})$, and we assume $\lambda_p \simeq \lambda$ in the region of $P_K < 600$ MeV. There is a “peak” in each of our calculated curves of the MFP, which is referred to the factor $f_1 = 0$, corresponds to the position of $M_N + E_K = M_\Sigma + M_\pi$. By comparing the results of different imaginary potential parameter $W_0$ with the $\lambda_p$, and considering $\lambda > \lambda_p$ and $\lambda \simeq \lambda_p$, we think the most possible imaginary depth parameter $W_0$ should be $\sim 65$ MeV.

If one takes the coupling constant $g_{\sigma K}$ to be a free parameter, the different real potential depths can be obtained by adjusting $g_{\sigma K}$. With $W_0 = 65$ MeV (the corresponding form factor parameter $\beta = 0.44$ GeV), the mean free paths are calculated for the different real potential depths $V_0 = 83, 99, 146$ MeV (the corresponding coupling constant $g_{\sigma K} = 1.044, 2.088, 5.44$), which are shown in Fig. 4(b). The corresponding real and imaginary parts of the optical potentials are also shown in Fig. 4(c). The form factor parameters of the real potential ( $\kappa = 0.285, 0.255$ GeV correspond to $g_{\sigma K} = 1.044, 5.44$, respectively) are determined by fitting the $K^-$ nucleus scattering data (which are shown in Fig. 2(c, d)). From Fig. 4(b), we can see that our calculations of $V_0 = 83$ MeV are most compatible with the $\lambda_p$ from $K^-p$ scattering data. And in Fig. 4(c), with $V_0 = 83$ MeV and $W_0 = 65$ MeV, both the real and imaginary potentials (the solid curves) of our calculations are very close to those of Jülich $KN$ interactions \[15\] (the star curves) in the range of $P_K < 100$ MeV. It is interesting that the recent experiment also indicated that the in-medium $K^-N$ potential depth is about $\sim 80$ MeV at normal nuclear density \[24\].

As a whole, with the constraints of the MFP from KN scattering data, we predicted that the
real potential depth is $V_0 \sim 80$ MeV, and the imaginary parameter $W_0 \sim 65$ MeV. One point must be emphasized, if the above results about the potential depths are right, according to our calculations on $K^-$-nuclei in [13], the sum of the half widths of the 1s and 1p states are larger than their separations in $K^-$-nuclei. In other words, no discrete $K^-$ bound states in the $A \geq 12$ nuclei can be found in experiments.

In conclusion, the momentum dependence of $K^-$-nucleus potentials have been studied in the framework of RMF theory. We think that the interior structure of a kaon may be one of the origin of the momentum dependence, and introduce a “form factor” to correct both the real and imaginary parts of the potential. It is found that the real part of the optical potentials decrease with increasing $K^-$ momenta, however the imaginary potentials increase at first with increasing momenta up to $P_k = 450 \sim 550$ MeV and then decrease. The effects of the exponential form factor on real and imaginary potentials are important. Analyzing several cases on both the real and imaginary potential depths, we predicted that the real potential depth is $V_0 \sim 80$ MeV, and the imaginary parameter $W_0 \sim 65$ MeV with the constraints of the MFP from KN scattering data.
