Abstract. A weak-lensing analysis of a wide-field V-band image centered on the cluster Abell 1942 has uncovered the presence of a mass concentration projected ∼ 7 arcminutes South of the cluster center. From an additional wide-field image, taken with a different camera in the I-band, the presence of this mass concentration is confirmed. A statistical analysis, using the aperture mass technique, shows that the probability of finding such a mass concentration from a random alignment of background galaxies is $10^{-5}$ and $4 \times 10^{-4}$ for the V- and I-band image, respectively. No obvious strong concentration of bright galaxies is seen at the position of the mass concentration, but a slight galaxy number overdensity is present about 1′ away from its center. Archival ROSAT-HRI data show the presence of a weak extended X-ray source near to the mass concentration, but also displaced by about 1′ from its center, and very close to the center of the slight galaxy number concentration.

From the spatial dependence of the tangential alignment around the center of the mass concentration, a rough mass estimate can be obtained which depends strongly on the assumed redshift of the lens and the redshift distribution of the background galaxies. A lower bound on the mass inside a sphere of radius $0.5h^{-1}$ Mpc is $1 \times 10^{14}M_{\odot}$, considerably higher than crude mass estimates based on the X-ray data; shifting the lens to higher redshift increases both the lensing and X-ray mass estimates, but does not resolve the mass discrepancy.

Concerning the nature of the mass concentration, no firm conclusion can be obtained from the available data. If it were a high-redshift cluster, the weak X-ray flux would indicate that it had an untypically low X-ray luminosity for its mass; if the X-ray emission were physically unrelated to the mass concentration, e.g., coming from a relatively low-redshift group which shows up in the number density of galaxies, this conclusion would be even stronger.

Since the search for massive halos by weak lensing enables us for the first time to select halos based on their mass properties only, it is possible that new types of objects can be detected, e.g., halos with very little X-ray and/or optical luminosity, should they exist. The mass concentration in the field of A1942 may be the first example of such a halo. Possibilities to establish the nature of this mass concentration with future observations are briefly discussed.

Key words: Cosmology: dark matter, gravitational lenses

1. Introduction

The abundance of clusters of galaxies as a function of mass and redshift provides one of the most sensitive cosmological tests (e.g., Richstone et al. 1992; Bartelmann et al. 1993). In particular, in a high-density Universe, the abundance of massive clusters strongly decreases with redshift,
so that the existence of a few massive high-redshift clusters can in principle rule out an $\Omega_0 = 1$ model (e.g., Eke et al. 1996; Bahcall & Fan 1998).

The reliability of the test depends on the detection efficiency and selection effects in existing samples of clusters whose understanding may be critical. Currently, clusters are selected either by their optical appearance as overdensities of galaxies projected onto the sky and/or in color-magnitude diagrams, or by their X-ray emission. Both selection techniques may bias the resulting sample towards high-luminosity objects, i.e. they would under-represent clusters with high mass-to-(optical or X-ray) light ratio. Furthermore, the observed properties have to be related to their mass in order to compare the observed abundance to cosmological predictions. The usual procedures consist in assuming a dynamical and/or hydrostatic equilibrium state as well as the geometry of the mass distribution, which in general may be questionable and fairly poorly justified from a theoretical point of view.

Indeed, whereas cosmological theories have made great progress in their ability to predict the distribution of dark matter in the Universe, either analytically or numerically (e.g., Lacey & Cole 1993; Jenkins et al. 1998), the luminous properties of matter are much more difficult to model. For example, to relate the X-ray data of a cluster to its mass, a redshift–dependent luminosity–temperature relation needs to be employed (see Borgani et al. 1999 and references therein), in the absence of a detailed understanding of the physics in the intra-cluster gas. It would therefore be of considerable interest to be able to define a sample of ‘clusters’ – or more precisely, dark matter halos – which can be directly compared with the predictions coming from N-body simulations.

Weak gravitational lensing offers an attractive possibility to detect dark matter halos by their mass properties only. A mass concentration produces a tidal gravitational field which distorts the light bundles from background sources. Owing to their assumed random intrinsic orientation, this tidal field can be detected statistically as a coherent tangential alignment of galaxy images around the mass concentration. A method to quantify this tangential alignment was originally introduced by Kaiser et al. (1994) to obtain lower bounds on cluster masses, and later generalized and proposed as a tool for the search of dark matter halos (Schneider 1996). This so-called aperture mass method can be applied to blank field imaging surveys to detect peaks in the projected density field. Combining halo abundance predictions from Press & Schechter (1974) theory with the universal density profile found in N-body simulations (Navarro et al. 1997), Kruse & Schneider (1999) estimated the number density of dark matter halos detectable with this method (with a signal-to-noise threshold of 5) to be of order 10 deg$^{-2}$, for a number density of 30 galaxies/arcmin$^2$, and depending on the cosmological model. These predictions were confirmed (Reblinsky et al. 1999) in ray-tracing simulations (Jain et al. 1999) through numerically-generated cosmic density fields.

In this paper, we report the first detection of a dark matter halo not obviously associated with light, using the above-mentioned weak lensing technique. Using a 14′ ×14′ deep V-band image, obtained with MOCAM at CFHT, we aimed to investigate the projected mass profile of the cluster Abell 1942 on which the image is centered. We found a highly significant peak in the reconstructed mass map, in addition to that corresponding to the cluster itself. This second peak, located about 7′ South of the cluster center, shows up in the alignment statistics of background galaxy images with a significance > 99.99%, as obtained from Monte-Carlo simulations which randomized the orientation of these background galaxies. An additional deep I-band image, taken with the UH8K at CFHT, confirms the presence of the mass peak. No obvious large overdensity of galaxies is seen at this location, implying either a mass concentration with low light-to-mass ratio, or a halo at substantially higher redshift than A1942 itself. Finally, an analysis of an archival ROSAT/HRI image of A1942 shows, in addition to the emission from the cluster, a 3.2–$\sigma$ detection of a source with position close to the peak in the projected mass maps; though this weak detection would be of no significance by itself, the positional coincidence with the ‘dark’ clump suggests that it corresponds to the same halo, and that it may be due to a high-redshift ($z \geq 0.5$) cluster.

The outline of the paper is as follows: in Sect. 2 we describe the observations and data reduction techniques, as well as the measurement of galaxy ellipticities which we employed. The aperture mass statistics is briefly described in Sect. 3.1 and applied to the optical data sets, together with a determination of the peak detection significance. Properties of the mass concentration as derived from the optical data sets and the X-ray data are discussed in Sects. 3.2 and 3.3, respectively, and a discussion of our findings is provided in Sect. 4. We shall concentrate in this paper mainly on the ‘dark’ clump; an analysis of the mass profile of the cluster A1942 and the reliability of mass reconstruction will be published elsewhere (van Waerebeke et al., in preparation)

2. Summary of optical observations and image processing

The V- and I-band observations were obtained at the prime focus of CFHT with the MOCAM and the UH8K cameras, respectively. Both observing procedures were similar, with elementary exposure time of 1800 seconds each in V and 1200 seconds in I. A small shift of 10 arc-seconds between pointings was applied in order to remove cosmic rays and to prepare a super-flatfield.

The V-band images were obtained during an observing run in dark time of June 1995 with the 4K ×4K mosaic camera MOCAM (Cuillandre et al 1997). Each individual
Fig. 1. The geometry of the optical data used in this paper. The left-hand side shows the area of the V-band MOCAM field (square) and the I-band UH8K-chip3 data (rectangle). The framed regions are 3.3 × 3.3 cutouts around the cluster center of A1942 and around our ‘dark clump’ candidate. These regions are zoomed in on the right-hand side. The ‘dark clump’ region is centered around α(J2000)=14^h 38^m 22.59^s; δ(J2000)=03° 32′ 32.22″.

chip is a 2K × 2K LORAL CCD, with 0′′.206 per pixel, so the total field-of-view is 14′ × 14′. Nine images have been re-centered and co-added, to produce a final frame with a total exposure time of 4h30min. The seeing of the coadded image is 0′′.74.

The I-band images were obtained with the 8K × 8K mosaic camera UH8K (Luppino, Bredthauer & Geary, 1994). Each individual chip is a 2K × 4K LORAL CCD, also with 0′′.206 per pixel, giving a field-of-view of 28′ × 28′. The final centered coadded image resulting from 9 sub-images has a total exposure time of 3h and a seeing of 0′′.67. The V- and I-band images have been processed in a similar manner, using standard IRAF procedures and some more specific ones developed at CFHT and at the TERAPIX\(^1\) data center for large-field CCD cameras. None of these procedures had innovative algorithms, so there is basically no difference in the pre-processing and processing of the MOCAM and UH8K images. For the present paper, we use only Chip 3 of the UH8K I-band image which contains the cluster A1942, and the additional mass concentration discussed further below. Fig. 1 shows the CCD images from both fields and their relative geometry.

A first object detection and the photometry have been performed with SExtractor2.0.17 (Bertin & Arnouts 1996). The MOCAM field has been calibrated using the photometric standard stars of the Landolt field SA110 (Landolt 1992), and the UH8K field was calibrated using the Landolt fields SA104 and SA110. The completeness limit is V = 26 and I = 24.5.

The lensing analysis was done with the imcat software, based on the method for analysing weak shear data by Kaiser, Squires & Broadhurst (1995), with modifications described in Luppino & Kaiser (1997) and Hoekstra et al. (1998; hereafter HFKS98). This method is based on calculations of weighted moments of the light distribution. Imcat is specifically designed for the measurement of ellipticities of faint and small galaxy images, and their correction for the smearing of images by a PSF, and for any anisotropy of the PSF which could mimic a shear signal.

\(^1\) http://terapix.iap.fr
These corrections are employed by the relation
\[
\chi = \chi^0 + P^\gamma \gamma + P^{\text{sm}} p ,
\] (1)
where \(\chi\) is the observed image ellipticity (defined as in, e.g., Schneider & Seitz 1995), \(\chi^0\) is the ellipticity of the unlensed source smeared by the isotropic part of the PSF, \(P^\gamma\) is the response tensor of the image ellipticity to a shear, and \(P^{\text{sm}}\) is the response tensor to an anisotropic part of the PSF, characterized by \(p\). These tensors are calculated for each galaxy image individually. Since the expectation value of \(\chi^0\) in (1) is zero, one obtains an unbiased estimate of the shear through
\[
\hat{\gamma} = (P^\gamma)^{-1} [\chi - P^{\text{sm}} p] .
\] (2)
(\(\hat{\gamma}\) is in reality an estimate for the reduced shear \(\gamma/(1 - \kappa)\) which reduces to the shear if \(\kappa \ll 1\).) The PSF anisotropy in our images is fairly small and regular over the field. We selected bright, unsaturated stars from a size vs. magnitude plot (see Fig. 2) and determined their ellipticities. As Fig. 3 shows, the stellar ellipticity changes very smoothly over the fields so that its behaviour can be easily fit with a second-order polynomial (see also Fig. 4). With these polynomials we performed the anisotropy correction in (1). We follow the prescription of HFKS98 for the calculation of \(P^\gamma\), and used the full tensors, not just their trace-part, in (2).

The current version of imcat does not give information about the quality of objects; for this we produced a SExtractor (version 2.0.20) catalog containing all objects that had at least six connected pixels with 1-\(\sigma\) above the local sky background. From this catalog we sorted out all objects with potential problems for shape estimation (like being deblended with another object or having a close neighbour). This included all objects with \(\text{FLAGS} \geq 2\) (internal SExtractor flag). The remaining catalog was matched with the corresponding imcat catalog, using a maximum positional difference of three pixels, and keeping only those objects for which the detection signal-to-noise of imcat was \(\geq 7\).

This procedure left us with 4190 objects (\(V > 22.0\)) for the MOCAM and 1708 objects (\(I > 21.0\)) for the \(I\)-band chip3. With these final catalogs all subsequent analysis
was done. We note that we did not cross-correlate the MOCAM and UH8K catalogs; hence, the galaxies taken from both catalogs will be different even in the region of overlap. Due to the different waveband used for object selection, the redshift distribution of the background galaxies selected on the MOCAM and the UH8K-chip3 frame can be different.

3. Analysis of the ‘dark’ clump

3.1. Weak lensing analysis

From the image ellipticities of ‘background’ galaxies, we have first reconstructed the two-dimensional mass map of the cluster field from the MOCAM data, using the maximum-likelihood method described in Bartelmann et al. (1996) and independently, the method described in Seitz & Schneider (1998). The resulting mass maps are very similar, and we show the former of these only.

In the left panel of Fig. 5, we show the resulting mass map with the (mass-sheet degeneracy) transformation parameter $\lambda$ chosen such that $\langle \kappa \rangle = 0$ (see Schneider & Seitz 1995), together with contours of the smoothed number density of bright galaxies. In general, this number density correlates quite well with the reconstructed surface mass density. As can be seen, a prominent mass peak shows up centered right on the brightest cluster galaxy.

In addition to this mass peak, several other peaks are present in the mass map. Such peaks may partly be due to noise coming from the intrinsic image ellipticities and, to a lesser degree, to errors in the determination of image ellipticities. In order to test the statistical significance of the mass peaks, we used the aperture mass method (Schneider 1996).

Let $U(\vartheta)$ be a filter function which vanishes for $\vartheta \geq \vartheta_0$, and which has zero mean, $\int_0^{\vartheta_0} d\vartheta \vartheta U(\vartheta) = 0$. Then we define the aperture mass $M_{ap}(\vartheta)$ at position $\vartheta$ as

$$M_{ap}(\vartheta) = \int_{|\vartheta'| \leq \vartheta} d^2\vartheta' \kappa(\vartheta + \vartheta') U(|\vartheta'|).$$

Hence, $M_{ap}(\vartheta)$ is a filtered version of the density field $\kappa$; it is invariant with respect to adding a homogeneous mass sheet or a linear density field, and is positive if centered...
Fig. 4. The left panels show the raw imcat ellipticities from bright, unsaturated foreground stars in our fields (upper panels: MOCAM field; lower panels: UH8K chip). The right panels show the ellipticities after they have been corrected with a second-order polynomial as described in the text. The rms of the ellipticities after correction is typically 0.015.

on a mass peak with size comparable to the filter scale $\theta$. The nice feature about this aperture mass is that it can be expressed directly in terms of the shear, as

$$M_{\text{ap}}(\theta) = \int_{|\theta'| \leq \theta} d^2 \theta' \gamma_t(\theta'; \theta) Q(|\theta'|)$$

(Kaiser et al. 1994; Schneider 1996), where the filter function $Q(\theta) = 2\theta^{-2} \int_0^\theta d\theta' \theta' U(\theta') - U(\theta)$ is determined in terms of $U(\theta)$, and vanishes for $\theta \geq \theta$. The tangential shear $\gamma_t(\theta'; \theta)$ at relative position $\theta'$ with respect to $\theta$ is defined as

$$\gamma_t(\theta'; \theta) = -\Re \{ \gamma(\theta + \theta') e^{-2i\varphi'} \} ,$$

where $\varphi'$ is the polar angle of the vector $\theta'$. In the case of weak lensing ($\kappa \ll 1$), the observed image ellipticities $\hat{\gamma}$ from (2) are an unbiased estimator of the local shear, and so the aperture mass can be obtained by summing over image ellipticities as

$$M'_{\text{ap}}(\theta) = \frac{\pi \theta^2}{N} \sum_i \gamma_t(\theta) Q(|\theta_i - \theta|) ,$$

where the sum extends over all $N$ galaxy images with positions $\theta_i$ which are located within $\theta$ of $\theta$, and the tangential component $\gamma_t(\theta)$ of the image ellipticity relative to the position $\theta$ is defined in analogy to $\gamma_t$. In general, $M'_{\text{ap}}(\theta)$ is not an unbiased estimator of $M_{\text{ap}}(\theta)$ since the expectation value of $\hat{\gamma}$ is the reduced shear, not the shear itself. However, unless the aperture includes a strong mass clump where $\kappa$ is not small compared to unity, $M'_{\text{ap}}(\theta)$ will approximate $M_{\text{ap}}$ closely. But even if the weak-lensing approximation breaks down for part of the aperture, one can consider the quantity $M'_{\text{ap}}(\theta)$ in its own right, representing the tangential alignment of galaxy images with respect to the point $\theta$. This interpretation also remains valid if the aperture is centered on a position which is less than $\theta$ away from the boundary of the data field, so that part of the aperture is located outside the data field, in which case $M'_{\text{ap}}(\theta)$ will not be a reliable estimator of $M_{\text{ap}}(\theta)$.

In order to determine the significance of the peaks in the mass map shown in Fig. 5, we have calculated $M'_\text{ap}$ on a grid of points $\theta$ over the data field, for four values of the filter scale $\theta$. Then, we have randomized the posi-
Fig. 5. The figure shows mass reconstructions and galaxy number density from the MOCAM field (left panel) and the UH8K-chip3 (right panel). The white contours show $\kappa = 0.03, 0.05, 0.07, 0.1, 0.12, 0.15, 0.17$ and $0.2$. For the reconstruction the shear was smoothed with a Gaussian of $\sigma = 40''$ width. The black contours show the smoothed galaxy distribution from all galaxies brighter than $V = 21.0$ and $I = 20.0$ (the smoothing kernel here was a Gaussian with $\sigma = 20''$).

Fig. 6 displays the contours of constant $\nu$, for different filter radii, varying from $80''$ to $200''$. As can be seen, the cluster center shows up prominently in the $\nu$-map on all scales. In addition, two highly significant peaks show up, one at the upper right corner, the other $\sim 7''$ South of the cluster center, close to the edge of the MOCAM field. We have verified the robustness of this Southern peak by using SExtractor ellipticities instead of those from imcat, and found both the cluster components and the Southern peak also with that catalog (although it should be much less suited for weak lensing techniques).

After these findings, we obtained the UH8K $I$-band image, on which both the cluster and the Southern mass peak are located on Chip 3. The mass reconstruction from galaxy images on Chip 3 are shown in the right panel of Fig. 5, from which we see that the cluster and this Southern mass peak also show up. Repeating the aperture mass statistics for Chip 3, we obtain the error levels as shown in Fig. 7; again, this Southern peak shows up at very high significance. Whereas the third peak in the significance maps (considering the two larger filter scales) from Chip 3, about halfway between cluster and the Southern component and slightly to the West, is also quite significant and is also seen in the corresponding MOCAM map (and most likely also corresponds to a mass peak, though a highly elongated one for which the aperture mass is less sensitive), we shall concentrate on the Southern peak, which we call, for lack of a better name, the ‘dark clump’.

In fact, as can be seen from Figures 1 and 5, this mass peak does not seem to be associated with any concentration of brighter galaxies. This could mean two things: either, the mass concentration is in fact associated with little light, or is at much higher redshift than A1942 itself.

Concentrating on the location of the dark clump, we determined the probability distribution $p_0(M'_{\text{ap}})$ for the value of $M'_{\text{ap}}$, obtained from $2 \times 10^6$ randomizations of the galaxy orientations within $160''$ of the dark clump. This probability distribution is shown as the solid (from MOCAM) and dashed (from Chip 3) curve on the left of Fig. 8. These two distributions are very well approximated by a Gaussian, as expected from the central limit theorem. The value of $M'_{\text{ap}}$ at the dark clump is 0.0395 for MOCAM, and 0.0283 for Chip 3. The fact that these two values are different is not problematic, since for Chip
3, the whole aperture fits inside the data field, whereas it is partially outside for MOCAM; hence, the two values of $M'_{\text{ap}}$ measure a different tangential alignment. Also, since the two data sets use galaxies selected in a different waveband, their redshift distribution can be different, yielding different values of the resulting lens strength. The probability that a randomization of image orientations yields a value of $M'_{\text{ap}}$ larger than the observed one is $\sim 10^{-6}$ for the MOCAM field, and $4.2 \times 10^{-4}$ for Chip 3.

Next we investigate whether the highly significant value of $M'_{\text{ap}}$ at the dark clump comes from a few galaxy images only. For this, the sample of galaxy images inside the aperture was bootstrap resampled, to obtain the probability $p_{\text{boot}}(M'_{\text{ap}})$ that this resampling yields a particular value of $M'_{\text{ap}}$. This probability is also shown in Fig. 8. The probability that the bootstrapped value of $M'_{\text{ap}}$ is negative is $3.8 \times 10^{-4}$ for Chip 3, and $< 10^{-6}$ for the MOCAM peak.

The radial dependence of the tangential image ellipticity is considered next. Fig. 9 shows the mean tangential image ellipticity in annuli of width $20''$, both for the MOCAM and the UH8K data centered on the dark clump. The error bars show the 80% probability interval obtained again from bootstrapping. It is reassuring that the radial behaviour of $\langle \hat{\gamma}_t \rangle$ is very similar on the two data sets. In fact, owing to the different wavebands of the two data fields and the fact that the aperture does not fit inside the MOCAM field, this agreement is better than one might expect. The mean tangential ellipticity is positive over a large angular range; except for one of the inner bins (for which the error bar is fairly large), $\langle \hat{\gamma}_t \rangle$ is positive in all bins for $\theta \lesssim 150''$. This figure thus shows that the large
and significant value of $M'_{ap}$ at the dark clump is not dominated by galaxy images at a particular angular separation.

### 3.2. Properties of the dark clump

We now investigate some physical properties of our dark clump candidate. We first argue that it is very unlikely for our object to lie at a redshift higher than 1. For our magnitude limit of 24.5 in the I band we expect approximately 30 galaxies/(1′)². We used approximately half of them (see Sec. 2) as putative background galaxies for our analysis. The median of simulated redshift distributions that extend the CFRS data (Lilly et al. 1995) to fainter magnitude limits (Baugh, Cole & Frenk 1996) is at about $z \approx 0.7 - 0.8$. If we assume that all our galaxies lie in the extreme tail of these distributions, then $z = 1.0$ represents a good upper limit for the redshift of our clump. However, the lensing analysis of the high-redshift cluster MS1054–03 (Luppino & Kaiser 1997) may provide an indication for a somewhat larger mean source redshift.

Next we use Fig. 9 to obtain a crude estimate of the mass of this object. Although the tangential shear appears to be fairly small close to the center position of the clump, there is a region between $\sim 50''$ and $\sim 150''$ where the tangential shear is clearly positive and decreases smoothly with radius. If we describe the mass profile by an isothermal sphere, its velocity dispersion $\sigma_v$ would be given by

$$
\left(\frac{\sigma_v}{c}\right)^2 = \frac{1}{2\pi} (\gamma_t \theta) \left(\frac{D_{ds}}{D_s}\right)^{-1},
$$

where the product $\gamma_t \theta$ would be independent of $\theta$ for an isothermal sphere model, and the final term is the ratio lens-source to observer-source distance, averaged over the background galaxy population. Introducing fiducial parameters, this becomes

$$
\sigma_v = 1135 \sqrt{\frac{\gamma_{100}}{0.06}} \left(\frac{1}{3 \langle D_{ds}/D_s \rangle}\right) \text{km/s},
$$

where $\gamma_{100}$ is the tangential shear 100′′ from the mass center. Alternatively, we can express this result in terms of the mass within a sphere of radius $R$, $M(<R) = 2\sigma_v^2 R/G$; for example, within $R = 0.5 h^{-1}$ Mpc, we find

$$
M(<0.5 h^{-1} \text{Mpc}) = 2.9 \times 10^{14} h^{-1} M_\odot \frac{\gamma_{100}}{0.06} \frac{1}{3 \langle D_{ds}/D_s \rangle}.
$$

Whereas this model is quite crude, the largest uncertainty in quantitative mass estimates comes from the unknown redshift of the dark clump and the unknown redshift distribution of the background galaxy population. The mass is a monotonically increasing function of the lens redshift, and depends very strongly on the assumed mean source redshift, in particular for values of $z_d \gtrsim 0.5$.

With the I band data we now estimate the light coming from the dark clump. For this we created a SEXtractor catalog counting every connected area with at least 3 pixels 0.5σ above the sky background as a potential object. The flux of all these objects (except from obvious stars) in a circle of 100′′ radius around the clump center was summed up. We did the same in 32 control circles around ‘empty’ regions in the other UH8K chips. It turned out that the flux within the clump region is compatible with the mean flux of the control annuli, i.e., there is no overdensity of light at the position of the dark clump. So we took the 1-σ fluctuation of the fluxes in the control circles as a reasonable upper limit for the light coming from the dark clump. For converting the flux into a total I band magnitude we assumed that we are dominated by elliptical galaxies, using K corrections for this galaxy type calculated with the
latest version of the Bruzual & Charlot stellar population synthesis models for the spectrophotometric evolution of galaxies (Bruzual & Charlot 1993). From the total $I$ band magnitude we derived a bolometric magnitude and a bolometric luminosity using standard approximations. With a lower limit for the mass and an upper limit for the luminosity we can give lower limits for the mass to light ratio of our object. This is shown in Fig. 10 for different source redshift distributions and two cosmologies. We see that the EdS universe gives fairly high $M/L$ estimates in comparison to a $\Omega = 0.3$, $\Lambda = 0.7$ model. When we assume a redshift of $z \approx 0.8$ for our clump we obtain a lower limit of $M/L \approx 300$ in the $\Lambda$ cosmology. This is a conservative lower limit which could be lowered significantly only if one assumes that the redshift distribution of the faint galaxies extends to substantially higher redshift.

As the dark clump has a mass characteristic of massive clusters it is of interest to search for X-ray emission associated with it.

### 3.3. The X-Ray data analysis

A1942 was observed by the ROSAT HRI in August 1995. The total integration time was 44,515 s. We retrieved the X-ray images from the public archive and reduced them using ESAS, Snowden’s code especially developed for the analysis of extended sources in ROSAT data (Snowden et al 1994; Snowden & Kuntz 1998).

The region showing a significant peak in the weak lensing reconstructed mass map is within the field of view of
the HRI image of A1942. We have searched for X-ray emission in this area. First of all, we have refined the astrometry in the X-ray image matching X-ray point sources to objects in our deep optical images. The astrometric offset from the original instrument coordinates is 3.5". There is a significant X-ray emission peak centered at 14\textsuperscript{h} 38\textsuperscript{m} 22.8\textsuperscript{s}, 3\textdegree 33' 11'' (J2000.0). This position is 60'' away from the weak lensing mass peak. The X-ray source is detected at the 3.2-\sigma level using an aperture of 30'' radius. Although the number of counts detected is low, its distribution is inconsistent with a point-like source, showing a profile elongated along the NW-SE direction that is broader than the instrumental PSF.

We have measured the source count-rate using concentric circular apertures centered on the X-ray emission peak. We obtain a count-rate of $7.4 \pm 2.5 \times 10^{-4}$ s$^{-1}$ within a circular aperture of 45'' radius. The counts still increase somewhat at larger radii but the measurement is much noisier given the uncertainty in the sky determination. The total flux is thus approximately 10-30\% larger than the above value. We convert the count-rate into a flux assuming an incident spectrum of $T = 3$ keV and a local hydrogen column density of $N_H = 2.61 \times 10^{21}$ cm$^{-2}$. The resulting unabsorbed flux is $3.4 \pm 1.2 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ in the 0.1-2.4 keV band. We have also fitted a standard beta profile (Cavaliere & Fusco-Fermiano 1978) to the azimuthally averaged radial profile. We obtain best values for the core radius and beta parameter (slope decline at large radii) of 15'' and 0.80, respectively, although these values are quite uncertain given the low total number of counts.

The X-ray luminosity depends on the redshift of the source. Assuming an incident spectrum at the detector of $T = 3$ keV [$T = 3(1+z)$keV at the source], the rest-frame
Fig. 10. Estimate of the lensing mass (upper left panel), an upper bound for the luminosity of the lens (upper right panel), and a lower limit on the mass-to-light ratio (lower panel), as a function of assumed lens redshift. All estimates are for an aperture size of 100″. The solid, short dashed and long dashed curves show the $M/L$ ratio in an EdS universe for $\langle z_s \rangle = 0.8$, $\langle z_s \rangle = 0.9$ and $\langle z_s \rangle = 1.0$. The dotted, dot-short dashed and dot-long dashed curves show the same in an $\Omega = 0.3$, $\Lambda = 0.7$ universe. We have assumed a redshift distribution $\propto z^2 \exp[-(z/z_0)^{3/2}]$ for the source galaxies; hence $\langle z_s \rangle \approx 1.5 z_0$. A value of $\gamma_{100} = 0.06$ was assumed.

X-ray luminosity in the 0.1-2.4 keV band would range from $1.9 \pm 2.5 \times 10^{42} h^{-2}$ erg s$^{-1}$ if the redshift is the same as that of A1942 ($z = 0.223$) to $3.5 \pm 0.5 \times 10^{43} h^{-2}$ erg s$^{-1}$ if $z = 1.0$ ($q_o = 0.5$).

We have also made a crude estimate of the mass of the system. On the one hand, if we assume an X-ray luminosity–temperature relation (e.g., Reichart et al 1999, Arnaud & Evrard 1999) and a temperature–mass relation (e.g., Mohr et al 1999), we can get mass estimates at a $0.5h^{-1}$ Mpc radius from $1.5 \times 10^{13} h^{-1} M_\odot$ at $z = 0.223$ to $1.6 \times 10^{14} h^{-1} M_\odot$ at $z = 1$ ($q_o = 0.5$). We can also assume a beta profile, fixing the core radius and the beta parameter, and compute the normalization necessary to obtain the observed flux at the measured radius. Then we can integrate the profile to obtain the gas mass. If we further assume a gas fraction, we can also obtain a total mass estimate. If we take the values obtained from our previous fit of the X-ray surface brightness profile, we get total masses at a radius of $0.5h^{-1}$ Mpc, of $9.2 \times 10^{12} h^{-1} M_\odot$ at $z = 0.223$ and $2.3 \times 10^{13} h^{-1} M_\odot$ at $z = 1$ ($q_o = 0.5$). Note the difference of a factor of 1.5 and 7 compared to the previous estimates. This gives an indication of the errors involved. If instead we were to use typical values of the core radius and beta parameter of most clusters of galaxies (e.g., $r_c = 0.125 h^{-1}$ Mpc and $\beta = 2/3$) the mass estimates would be approximately a factor 3 larger and closer to the estimates using standard correlations.
Although we have presented quantitative values for the mass of the system based on the X-ray data, these should be taken only as informative given the assumptions and errors involved. Our main point in presenting these estimates is to show that this system has the X-ray properties of a galaxy group if it is at the same redshift of A1942. The lensing shear signal measured would then be too large for such a group unless it had a remarkable unusually high mass-to-X-ray light ratio. It seems more plausible that the system is a more massive cluster of galaxies at a higher redshift if the X-ray and lensing signal do indeed come from the same source, although the X-ray derived mass is still lower than the one obtained from the shear signal. The small angular scale X-ray core radius (larger physical scale if at larger redshift) and the lack of bright galaxies also point towards the same conclusion.

As an alternative, the X-ray emission may be unrelated to the dark clump, but associated with the small galaxy number overdensity projected near it, as seen from the black contours in the right-hand panel of Fig. 5. In that case, both the local enhancement of the galaxy density and the X-ray emission may be compatible with a group of galaxies, rather than a massive cluster, as indicated by the weak lensing analysis.

4. Discussion and conclusions

Using weak lensing analysis on a deep high-quality wide-field V-band image centered on the cluster Abell 1942, we have detected a mass concentration some 7′ South of the cluster. This detection was confirmed by a deep I-band image. No clear overdensity of bright galaxies spatially
associated with this mass concentration is seen; therefore, we termed it the ‘dark clump’. A slight over-density of galaxies is seen ~ 1’ away from the mass center of the dark clump, but it is unclear at present whether it is physically associated with the mass concentration. Archival X-ray data allowed us to detect a 3.2-σ X-ray source near the dark clump, separated by 60 arcseconds from its peak; it appears to be extended. The X-ray source is spatially coincident with the slight galaxy overdensity.

We have estimated the significance of the detection of this mass peak, using several methods. For the V-band image, the probability that this mass peak is caused by random noise of the intrinsic galaxy ellipticities is ~ 10^{-6}; a similar estimate from the I-band image yields a probability of ~ 4 × 10^{-4}. Thus, the mass peak is detected with extremely high statistical significance. A bootstrapping analysis has shown that the tangential image alignment is not dominated by a few galaxy images, as also confirmed by the smooth dependence of the tangential shear on the angular separation from its center. Whereas these statistical tests cannot exclude any systematic effect during observations, data reduction, and ellipticity determination, the fact that this dark clump is seen in two independent images, taken in different filters and with different cameras, make such systematics as the cause for the strong alignment highly unlikely. Although we have accounted for the slight anisotropy of the PSF, the uncorrected image ellipticities yield approximately the same result.

A simple mass estimate of the dark clump shows it to be truly massive, with the exact value depending strongly on its redshift and the redshift distribution of the faint background galaxies. The mass inside a sphere of radius 0.5h^{-1} Mpc is ≥ 10^{14} h^{-1} M_\odot, if an isothermal sphere model is assumed; if the lens redshift is larger, this lower mass limit increases, by about a factor 2 for z ~ 0.5 and a factor of about 10 for z ~ 1. In any case, this mass estimate appears to be incompatible with the X-ray flux if the dark clump corresponds to a ‘normal cluster’, at any redshift. We therefore conclude that the mass concentration, though of a mass that is characteristic of a massive cluster, is not a typical cluster. This conclusion is independent of whether the X-ray emission is physically associated with the dark clump or not.

The fact that the tangential shear decreases towards the dark clump, may best be interpreted as a non-relaxed halo.

Further observations may elucidate the nature of this mass concentration. Deep infrared images of this region will allow us to check whether an overdensity of IR-selected galaxies can be detected, as would be expected for a high-redshift cluster, together with an early-type sequence in the color-magnitude diagram. A deep image with the Hubble Space Telescope would yield a high-resolution mass map of the dark clump, owing to the large number density of galaxies for which a shape can be measured, and thus determine its radial profile with better accuracy. Images in additional (optical and IR) wavebands can be used to estimate photometric redshifts for the background galaxies. In conjunction with an HST image, one might obtain ‘tomographic’ information, i.e., measuring the lens strength as a function of background source redshift; this would then yield an estimate of the lens redshift. The upcoming X-ray missions will be considerably more sensitive than the ROSAT HRI and will therefore be able to study the nature of the X-ray source in much more detail. And finally, one could seek a Sunyaev-Zel’dovich signature towards the dark clump; its redshift-independence may be ideal to verify the nature of a high-redshift mass concentration.

But whatever the interpretation at this point, one must bear in mind that weak lensing opens up a new channel for the detection of massive halos in the Universe, so that one should perhaps not be surprised to find a new class of objects, or members of a class of objects with unusual properties. The potential consequences of the existence of such highly underluminous objects may be far reaching: if, besides the known optical and X-ray luminous clusters,
a population of far less luminous dark matter halos exist, the normalization of the power spectrum may need to be revised, and the estimate of the mean mass density of the Universe from its luminosity density and an average mass-to-light ratio may change. We also remind the reader that already for one cluster, MS1224, an apparently very high mass-to-light ratio has been inferred by two completely independent studies (Fahlman et al. 1994; Fischer 1999).
