Purpose: Reducing preoperative fasting time showed positive effects in several studies, and current guidelines suggest use of a preoperative oral carbohydrate-rich solution before elective surgeries. For elective colectomy procedures, some surgeons favor two-day bowel preparation with diet restriction and administration of laxatives. Aside from patients experiencing the discomfort of nil per os (NPO), there are reported benefits regarding intake of liquids until at least two hours prior to surgery, including decrease in insulin resistance, without additional postoperative surgical complications. The aim of this study is to show the benefits of administration of oral rehydration solution (ORS) two hours prior to surgery for patients undergoing elective colectomy, particularly postoperative insulin resistance.

Methods: This is a randomized controlled trial. All patients undergoing elective colectomy were included and randomized to the control arm or treatment arm. The control arm consisted of the standard bowel preparation and one day of NPO, while the treatment arm consisted of the standard bowel preparation and allowing intake of carbohydrate-rich ORS until 2 hours before surgery. The insulin, glucose, cortisol, and triglyceride levels were determined immediately after induction, 6 hours, 24 hours, and 48 hours post-op, and compared. The homeostatic model assessment-insulin resistance, insulin, glucose, cortisol, and triglyceride levels were determined and compared between the two groups. Anxiety and postoperative complications were monitored and assessed as well.

Results: There was less insulin resistance in patients who received ORS 2 hours prior to surgery. Insulin, glucose, cortisol, and triglyceride levels were lower in the treatment group compared to the control group. Taking ORS 1 day prior and until 2 hours before surgery decreased anxiety and discomfort, and alleviated hunger.

Conclusion: Regarding complications, there was no difference in the incidence of aspiration and postoperative complications. There were fewer wound complications and incidence of paralytic ileus in the treatment group.

Key Words: Preoperative fasting, Insulin resistance, Oral carbohydrate-rich solution

INTRODUCTION

Reducing preoperative fasting time showed positive effects in several studies, and current guidelines suggest using preoperative oral carbohydrate-rich solution before elective surgeries. This can reduce postoperative com-
Effects of Preoperative Oral Carbohydrate-Rich Solution

Complications and enhance early recovery.

For elective colectomy procedures, some surgeons favor bowel preparation two days prior to the surgery. Osmotic laxatives such as CoLyte (Pendopharm Co., Canada) are administered two days prior, and nil per os (NPO) is required 1 day prior to ensure no fecal residue is left in the bowel. Though it may ensure a cleaner and safer surgery, this longer period of starvation increases insulin resistance and may increase postoperative complications and morbidity.1-4 However, there is evidence that administration of carbohydrate-rich oral rehydration solution (ORS) at least two hours prior to surgery reduces insulin resistance, without increasing postoperative complications.1-4,6

Interplay of many factors can affect the glycemic state and insulin resistance in patients, especially those undergoing major abdominal surgery. We need to optimize preoperative care and preparation to prevent complications and enhance recovery, and this is one of the many points emphasized in Enhanced Recovery after Surgery (ERAS) protocol. Preoperative preparation, as well as the surgery itself, can induce a metabolic stress response and an inflammatory ripple known to be responsible for the catabolic response, muscle wasting, hyperglycemia, insulin resistance, which leads to delayed wound healing, prolonged ileus, and other adverse outcomes.6

Preoperative oral carbohydrate-rich solutions given at least 2 hours prior to major abdominal surgery may decrease insulin resistance and its negative effects. Based on previous studies, patients should be fed with a controlled volume at specified times.6 This can cause patient discomfort and anxiety. With this background, our purpose is to evaluate the difference of insulin resistance in those who received ORS 1 day until 2 hours prior to surgery and those who did not. We want to show the benefit of freely drinking a carbohydrate-rich ORS, not limited by a specified volume or time, except until 2 hours before surgery.

MATERIALS AND METHODS

1. Objectives

The objective of this study is to determine if ORS administration for patients undergoing elective colon surgery will decrease insulin resistance.

The primary endpoint is to compare changes in homeostatic model assessment-insulin resistance (HOMA-IR) levels between the treatment and the control group.
The secondary endpoints are to compare changes in insulin levels, glucose levels, cortisol and triglyceride levels. The pain scale will be evaluated using the visual analogue scale (VAS), including stress relief from shorter NPO period. The postoperative surgical complications will be evaluated and compared as well (Fig. 1).

2. Study setting
This study has been reviewed and accepted by the Seoul National University Bundang Hospital Institutional Review Board (B-1310/224-007), Ethics Committee, and Clinicaltrial.gov Committee (NCT02062788).

The methodology of this research, the retrieval of its data and analysis are all in agreement with the fundamental spirit of Korea Good Clinical Practice and the Declaration of Helsinki. The research is conducted as according to the Korean law. The primary investigators are obligated to promptly report any approval or non-approval of the research proposal and/or its progress made by the IRB. The final report is also to be reported to the committee once the research is complete.

This is a randomized controlled trial conducted for 2 years from March 2014 to February 2016.

3. Study population
Based on a study by Viganò et al. about the effects of preoperative oral carbohydrate supplementation on postoperative metabolic stress response of patients undergoing abdominal surgery, we calculated our sample size, with a significance level of 5%, test power of 80%, and considered a dropout rate of 10%. The computed sample size is 71 subjects per arm, for a total of 142 patients.

1) Inclusion criteria
All subjects for elective colon surgery are randomized with the following inclusion criteria: adults 19-75 years of age, American Society of Anesthesiologists grade I–II, those who can take ORS with intact swallowing mechanism, body mass index of less than 27.5, Child-Turcotte-Pugh Classification score of less than 6, patients fluent in speaking and writing Korean.

2) Exclusion criteria
The exclusion criteria are as follows: emergency colon surgery (i.e., those with perforation or obstruction), abdominal distention, patients with comorbidities (i.e., diabetes mellitus, cerebrovascular accident, chronic obstructive pulmonary disease, end-stage renal disease, myocardial infarction, transient ischemic attack), those with aspiration tendencies, with food allergies, prior gastric surgery due to limitations of evaluation of gastric residue, and those with clinical T4 or M1 disease.

3) Treatment
All subjects who will undergo elective colectomy, from March 2014 to February 2016, that fulfill the inclusion and exclusion criteria, is randomized by the Medical Research Collaborating Center. This is an independent research center that determines that both arms in the study are evenly distributed.

Elective colectomy patients are typically administered with osmotic laxatives (Colyte) 2 days prior to the surgery and are kept under NPO one day prior to the day of surgery. Nutritional support during the fasting period is administered intravenously using dextrose solution. This will be the treatment for the control group.

The treatment group, on the other hand, is allowed to take ORS as tolerated one day prior to the surgery until two hours prior to surgery. The rest of the treatments are the same.

All patients will be asked to fill out a questionnaire prior to surgery. Serum glucose and insulin levels are obtained for four sequential times - right after induction, 6 hours, 24 hours, and 48 hours post-op, respectively. The samples will be collected opposite the IV site on the antecubital fossa. The HOMA-IR level is derived using the equation HOMA-IR Index equation (evaluation of Insulin resistance\(^{5-7}\))

\[
\text{HOMA-IR} = \text{Insulin (μU/mL)} \times \text{blood glucose (mg/dL)} / 405
\]

Serum triglyceride and cortisol levels will be obtained on two different occasions for comparison.

The gastric residual volume will be assessed after induction of anesthesia. A suction catheter is positioned in the stomach and aspirate samples are obtained using a syringe. The amount and pH levels (using pH meter) will
be measured and recorded.

The patients start sips of water followed by a full liquid diet on the 2nd postoperative day. After which, a soft blended diet is allowed on the 3rd postoperative day, and a full regular diet on the same day or the day after.

4) Study endpoints
To assess the primary endpoint, HOMA-IR, the mean and standard deviation of the two groups are compared from the continuous variable glucose and insulin values. We plot the data obtained from the two groups following a Gaussian distribution, comparing its values.

The secondary endpoints, including insulin, glucose, cortisol, and triglyceride levels will be recorded and compared. The VAS and anxiety will be evaluated, including postoperative complications such as pertaining to the surgical site (i.e., anastomotic leak, anastomotic bleeding, anastomotic breakdown, abscess formation, obstruction), wound (i.e., seroma, hematoma, infection, wound dehiscence), or return to bowel function (i.e., paralytic ileus).

The difference between the two groups will be compared using an independent t-test statistical analysis.

RESULTS
Given the studies and data about preoperative carbohydrate-rich drink administration for patients undergoing elective surgery, we expect that there is less insulin resistance in these patients compared to the group who had undergone a longer fasting period.

Insulin, glucose, cortisol, and triglyceride levels are lower in the treatment arm.

Preoperative oral carbohydrate-rich solution given freely 1 day until 2 hours prior to surgery decreases anxiety, discomfort, and alleviates thirst and hunger.

For complications, there is no difference in the incidence of aspiration and other postoperative complications, including anastomotic leak or breakdown, abscess formation, obstruction on both arms. Wound complications, such as surgical site infection, are lesser in the treatment arm, as well as incidence of paralytic ileus.

DISCUSSION
EREAS was introduced in the early 2000s by Kehlet and Wilmore, and was applied primaril to patients receivong colectomy. As the knowledge and understanding of this concept continues to grow, we are now able to change the way we treat pre- and postoperative patients. This includes patient preparation and intervention like preoperative optimization, preoperative bowel preparation, fasting, anesthetic medications, thromboembolic prophylaxis, antibiotic use, pain control, mobilization, nutritional support and so on. In Europe, it has been proven that applying this concept to patients resulted in decreased length of post-operative hospital stay, post-op complications and overall hospital costs.

Shortened preoperative fasting and carbohydrate-containing fluids preoperatively given 2 hours prior to surgery has been shown to be safe and beneficial to patients undergoing surgery. It has been shown to reduce patient thirst, stress and anxiety, postoperative protein and muscle loss, and insulin resistance.

Insulin resistance increases in procedures such as herniorrhaphy or laparoscopic cholecystectomy. Administration of preoperative carbohydrates decrease post-op nausea and vomiting, permits early postoperative feeding, accelerates recovery, thereby shortening hospital stay and costs.

Conventional pre-op 8 hour fasting increases insulin resistance and influences increased glucose levels. Insulin resistance has various impacts on the outcome and recovery of patients especially those undergoing major surgery. Therefore, primary care physicians, surgeons, anesthesiologists, and nutritionists aim to decrease risk factors for its development to enhance recovery and decrease complications that coincide with insulin resistance.

Intake of a carbohydrate-rich solution induces insulin release which is normally seen after intake of a meal. This prevents the various physiological mechanisms that occur with prolonged fasting, such as activation of gluconeogenesis, glycogenolysis, and oxidation of fatty acids. Liver glycogen stores are increased as much as 44% compared to those who have prolonged fasting times.

Additional benefits of shorter preoperative fasting include
decrease in patient discomfort from fasting state; helps stabilize postoperative glucose, triglyceride, and cortisol levels. Due to stimulation of the gut-associated lymphatic tissue through shorter preoperative fasting, this preserves intestinal barrier function, reduces bacterial translocation, which contributes to lesser postoperative infection rates.\textsuperscript{1-4,6,22-27}

In monitoring intraoperative and postoperative complications, there is no difference in the incidence of aspiration. Studies have shown that gastric emptying time for clear liquids, such as carbohydrate-rich solutions, is 120 minutes. Therefore, the 2-hour fasting time preoperatively is adequate and safe for patients.\textsuperscript{28}

Other postoperative complications, including anastomotic leak or breakdown, abscess formation, obstruction, will have no difference between the two groups.\textsuperscript{29} Wound healing and recovery is faster in the ORS group. This can be explained due to better glucose control and decreased insulin resistance. Insulin resistance impairs delays wound contraction, epithelialization and formation of granulation tissue essential for proper and lasting wound healing.\textsuperscript{29} Delayed wound healing and repair may also predispose patients to wound morbidity such as surgical site infections.

Overall, surgical patients will benefit with preoperative carbohydrate-rich solution as tolerated and shorter preoperative fasting periods. Giving carbohydrate-rich oral solution 2 hours preoperatively will decrease insulin resistance, have better glucose control, lower levels of insulin, cortisol, and triglycerides. Patient will experience greater comfort, lesser anxiety, hunger, and thirst; without increasing postoperative complications. It is safe as it is beneficial.
