Salivary Interleukin 1-beta levels and clinical periodontal parameters in habitual naswar users and non-users

Zaeem Arif Abbasi1, Naila Irum Hadi2, Adnan Mustafa Zubairi3, Mervyn Hosein4

ABSTRACT

Objectives: Aim of our study was to assess the expression of salivary Interleukin 1-beta (IL-1β) and clinical periodontal parameters in naswar users and non-users (controls).

Methods: Eighty four individuals (forty-two naswar users and forty-two controls) were included in the study which was conducted between August 2017 and May 2018. Salivary IL-1β levels, plaque index (PI), bleeding on probing (BOP), probing depth (PD) and clinical attachment loss (CAL) was assessed in all the participants.

Results: PD of 4mm (p<0.05), PD of 5-6mm (p<0.05), CAL (p<0.001) and levels of salivary IL1β (p<0.05) were significantly higher among naswar users as compared to controls while PI, BOP and number of missing teeth showed no significant difference among the two groups (p>0.05).

Conclusion: Periodontal inflammatory conditions were worse and salivary IL-1β levels were elevated in naswar users as compared to controls.

KEYWORDS: Inflammation, Interleukin (IL-1β), Naswar, Periodontitis, Saliva.

INTRODUCTION

Naswar is categorized as one of the smokeless tobacco products (STPs), the ingredients of which are mainly sundried crushed local tobacco, ash, calcium oxide (slaked lime), and sometimes flavoring agents (e.g., cardamom, menthol) as well as coloring agents (indigo).1 It is commonly used in Pakistan, Afghanistan, Iran, Central Asia and South Africa.1 Naswar usage is gaining popularity as it is now available and being consumed in different parts of the world including England.2 It is prepared and wrapped into small plastic bags which even lack safety warnings.1 It is used mostly by applying and retaining it in the vestibular cavity adjacent to the buccal or labial mucosa or at times under the tongue.2 All the other types of STPs are consumed via chewing but naswar is never bitten because of its bad taste.2

The tobacco being currently used in naswar contains trace amounts of arsenic, beryllium,
cadmium, chromium, cobalt, lead, nickel, nitrate, nitrite and tobacco specific nitrosamines (TSNAs). Along with these substances, addictive nicotine is also found in naswar. The main characteristics of chronic periodontitis are periodontal attachment loss, connective tissue degradation and resorption of alveolar bone. The disease process is initiated by bacterial pathogens however it has been proven that they alone cannot be responsible for the severity of tissue destruction occurring in periodontitis. Currently accepted theory related to pathogenesis of periodontitis suggests that alteration in host defenses by bacterial and host products stimulates the host inflammatory response, eventually causing tissue damage. Proinflammatory cytokines are considered to be important modulators of inflammation during the initiation and progression of periodontal disease. Interleukin (IL)-1, which is a proinflammatory cytokine plays a vital role in immune regulation that causes a variety of inflammatory responses. It has been identified as a periodontal disease marker because of its function as not only an inflammatory mediator but also as a modulator of extracellular matrix and bone. Although both types of IL-1 (IL-1α and IL-1β) have similar biologic functions, IL-1β is more effective in stimulating bone resorption and occurs more often in periodontitis. Use of smokeless tobacco products such as naswar is widespread in the population of Karachi, contributing to inflammatory, premalignant and malignant diseases of the oral cavity. To the best of our knowledge the effect of naswar on periodontal health in terms of salivary IL-1β levels has not been studied so far. Hence, IL-1β levels in association with clinical periodontal parameters will give a better understanding of the effects of naswar, specifically on the periodontium.

The objectives of our study were first to assess the clinical periodontal parameters and salivary IL-1β levels in naswar users and non-users and then to find a correlation of salivary IL-1β levels with clinical periodontal parameters.

**METHODS**

This study was conducted between August 2017 and May 2018. Convenience sampling technique was used for recruitment of participants from the dental outpatient department (OPD) of Ziauddin College of Dentistry, Ziauddin University, Karachi, Pakistan. A WHO Software (“Sample size determination in Health Sciences”) was used for sample size calculation using 0.2% prevalence of naswar use as reported by Sajid and Bano (2016) at 95% confidence interval and 80% power of study. This was a cross-sectional study with eighty-four participants, which were divided into two equal groups. Both genders were included with age’s ≥ 18 years. Individuals who reported consuming naswar daily for ≥ 1 year were defined as naswar users (Group-1). Controls included those who had never used tobacco in any form (Group-2). Individuals who were present or former users of any other type of tobacco or alcohol products; had systemic inflammatory diseases that could affect the periodontal condition; antibiotics and anti-inflammatory medication usage within 6 months or those who had any periodontal and/or orthodontic procedure in the past 6 months were excluded from the study.

This study was approved by the Ethical Review Committee (ERC) of Ziauddin University, Karachi, Pakistan (Reference code # 0300917ZAOP). It was obligatory for all participants to sign an informed written consent in order to take part in this study. A questionnaire was used to obtain data from all the participants regarding age, gender, ethnicity, educational status, habits related to naswar usage (time period since using, daily frequency, duration of holding a single bolus in the mouth, reason and location of naswar placing), oral hygiene practices and whether they considered naswar safe for consumption.

For collection of unstimulated whole saliva (UWS) samples, participants were asked to come in early morning hours. They were asked to refrain from eating or drinking at least two hours before saliva collection. For collection of saliva, the patient was first seated on a dental chair and asked to allow UWS to collect in the mouth for five minutes, which was then passively drooled into a graded plastic funnel tube. The samples were stored in a container filled with dry ice and immediately shifted to the Research Laboratory, Ziauddin University. Saliva samples were centrifuged at 2500 rpm (Gemmy Industrial Corp., USA) for 20 minutes at 4°C and the supernatant (around 3ml) was stored at -80°C in multiple aliquots.

A trained examiner (ZA) performed the clinical periodontal examination. The overall kappa for intra examiner reliability was 0.84. Full-mouth PI (plaque index), BOP (bleeding on probing), PD (probing depth) and CAL (clinical attachment loss) were measured at six sites per tooth (mesial, middle and
distal points on buccal/labial and lingual/palatal surfaces) on all teeth of both arches (excluding third molars). A University of North Carolina graded probe (Hu Friedy-15) was used to measure PD to the nearest millimeter.

For the quantitative determination of IL-1β concentration in saliva, (Glory Science Co., Ltd) human IL-1β enzyme linked immunosorbent assay (ELISA) kit was used. Manufacturer’s instructions were followed for the indirect ELISA technique being performed. A spectrophotometer (Plate reader stat, Fax-2100, Awareness technology, USA) was used to determine the absorbance by reading the plates at 450nm. This was done twice to check for reproducibility of the results. The detection limit of the kit was 1-20ng/L.

Statistical Package for the Social Sciences (SPSS version 20, Chicago, IL) was used for statistical analysis. After checking normality using Shapiro-Wilk’s test, Mann-Whitney test was run to compare PD, CAL, BI, and PI between naswar dippers and controls. Spearman’s correlation was computed to find the correlation between IL-1β with PD, CAL, BI and PI. A pValue less than .05 was set to show statistical significance of the findings.

RESULTS

A total of eighty-four male subjects were included in the study (forty-two naswar users and forty-two healthy controls). Only two females reported occasional naswar usage instead of habitual, hence they were excluded from the study. The mean age of naswar users and controls were 33.7 ± 10.8 and 36.4 ± 4.9 years, respectively (Table-I). Naswar dippers mostly belonged to the Pathan community (76.2%). Regarding educational status in naswar users and non-users, 59.5% and 36.4% were uneducated, respectively. Most common reason for using naswar was that they were just addicted to it (52.4%) (Table-I). About 81.1% reported placing it in the premolar-molar vestibular area (right, left or in combination). The mean duration of habit was 12.8 ± 8.1 years, whereas the mean duration of keeping a single naswar bolus was 7.2 ± 4.9 minutes (Table-I). An alarming 85.7% of the naswar dippers claimed that they considered naswar safe for consumption as it had no deleterious effect on the body, particularly oral cavity.

In maintaining oral hygiene, participants reported using brush, miswak and finger (with paste or tooth powder) for cleaning their teeth. Among naswar dippers, 35.7% reported brushing and 40.5% miswak use at least once a day (Table-I). It is pertinent to mention that in our part of the world use of Miswak is very popular as a tool for cleaning the teeth. Brushing habit in naswar users and controls were 35.7% and 40.4%, respectively. Use of miswak was found to be almost equivalent to brushing habits, that is in naswar users and controls it was 40.4% and 38.2%, respectively. About 23.9% of naswar dippers and 21.4% of controls reported that they did not use any technique for maintaining oral hygiene (Table-I).

CAL, PD of 4mm and in 5-6mm range was significantly higher in naswar dippers than controls. Difference in clinical parameters among naswar dippers and controls was significant. The results are shown in Table-I.
the two groups was determined by applying Mann-Whitney U test. There was no significant difference in PI, BI, PD > 7mm and the number of missing teeth (Table-II).

Mean Interleukin 1-β levels in naswar dippers and controls was 8.3 ± 3.1 ng/L and 2.3 ± 1.1 ng/L, respectively (Table-II). There was a significant positive correlation between values of CAL (P<0.01) PD 4mm and 5-6 mm (P<0.05) with salivary Interleukin 1-β levels after applying Spearman’s correlation test (Table-III).

**DISCUSSION**

To the best of our knowledge after going through published literature, this is the first study assessing salivary IL-1β level in naswar users. Multiple studies have shown that use of STPs including gutka, snus, shammah etc, have harmful effects on the oral cavity eventually leading to malignant lesions.13,14 Studies show that STPs use among Pakistani population is more in males then in females, and there is even a larger difference among the rural population.15,16 As mentioned before the use of naswar has become widespread and is gaining popularity, therefore researchers are now focusing on studies reporting the effects of naswar on the oral cavity. A study assessing cytomorphometric changes in buccal smear of naswar users, reported dysplastic changes in the oral mucosa, hence pointing to the potential of causing oral premalignant/malignant lesions as well.17 Recent studies have also associated naswar usage with alveolar bone loss and concurrent aggravation of clinical periodontal parameters.13,18 Contrary to our findings, a study assessed IL-1β levels in serum of naswar dippers which showed the levels to be significantly lowered in naswar users as compared to healthy controls.11 Present study showed that IL-1β level were raised in the saliva of naswar users as compared to the healthy controls. IL-1β levels in both GCF and saliva of other type of STP users, was also found to be raised; emphasizing the point that IL-1β plays a critical role in periodontitis and that its levels were increased more when associated with a risk factor such as use of STPs.14,19,20 This could be due to the fact that naswar users have a poorer periodontal condition as shown by elevated PD and CAL. An interesting finding in our study was that though there was very significant difference in CAL and PD of naswar users as compared to non-users, the alteration in PI, BOP and missing number of teeth wasn’t statistically significant. This could be attributed to the fact that naswar users have a poorer periodontal condition as shown by elevated PD and CAL. An interesting finding in our study was that though there was very significant difference in CAL and PD of naswar users as compared to non-users, the alteration in PI, BOP and missing number of teeth wasn’t statistically significant. This could be attributed to the fact that most of the study population belonged to low socioeconomic status and were mostly uneducated; hence there was poor oral hygiene maintenance in the healthy controls as well. Similarly a justification for an increased number of missing teeth could be due to these patients opting for extraction rather than costly but appropriate treatments such as fillings and root canals.

GCF is the primary source of periodontitis-associated cytokines and host-derived enzymes; however these substances will ultimately enter into the saliva.21,22 Though, mostly GCF is taken as a sample medium, it is very difficult because:

1. It is a technique sensitive method, as collection requires skilled person who can prevent contamination of the GCF strips or paper points from saliva;
Salivary IL-1 beta and periodontal parameters in naswar users

2. There are chances of bleeding when collecting GCF which again contaminates the sample;
3. GCF strips or paper points require an added electronic Periotron device to determine the volume obtained, which is not available easily;
4. Collecting GCF through micropipette may cause trauma to the gingiva as well. In addition to these, saliva collection is less troublesome and several samples can be collected without causing any distress to the patient, hence it was the selected medium for this study.21

In this study we attempted to see the use of naswar among various ethnicities residing in Karachi city namely Urdu speaking/Muhajir, Punjabi, Sindhi and Pathans as previously naswar dipping was considered to be specific to those belonging from Pathan ethnic group. Though they are still the most common users of the product, a rise in usage is seen in other communities as well which is also shown in other studies as well. 15 It is important for health care providers to have adequate knowledge regarding the detrimental effects of naswar usage so they can convey that knowledge to those who use this STP. There’s an alarming myth among the knowledge to those who use this STP. There’s an evidence of potential harmful effects of and may cause oral cancer. Due to increase in may have detrimental effects on the oral tissues cause trauma to the body internally. Only 14.3% of STPs and has no detrimental effects on the oral tissues it is safe for consumption as compared to other

**Future Recommendation:** Levels of IL-1β might be checked both in saliva and GCF of naswar users, thus drawing a comparison between the effectiveness of the two mediums.
