Quantifying the advantage of domain-specific pre-training on named entity recognition tasks in materials science

Highlights

- Efficient extraction of information from materials science literature is needed
- Domain-specific materials science pre-training improves results
- Even simpler domain-specific models can outperform more complex general models

In brief

Efficient automated extraction of information from materials science literature is needed due to an increasingly unwieldy number of publications. For a selection of materials science NER tasks, Trewartha et al. find that language models pre-trained on materials science literature provide measurable advantages over language models pre-trained on general literature or even scientific literature from multiple fields. This provides an opportunity to produce higher-quality results that require less training data in order to address this problem.
Quantifying the advantage of domain-specific pre-training on named entity recognition tasks in materials science

THE BIGGER PICTURE

A bottleneck in efficiently connecting new materials discoveries to established literature has arisen due to a massive increase in publications. Four different language models are trained to automatically collect important information from materials science articles. We compare a simple model (BiLSTM) with materials science knowledge to three variants of a more complex model: one with general knowledge (BERT), one with general scientific knowledge (SciBERT), and one with materials science knowledge (MatBERT). We find that MatBERT performs the best overall. This implies that language models with greater extents of materials science knowledge will perform better on materials science-related tasks. The simpler model even consistently outperforms BERT. Furthermore, the performance gaps grow when the models are given fewer examples of information extraction to learn from. MatBERT’s higher-quality results should accelerate the collection of information from materials science literature.

Development/Pre-production: Data science output has been rolled out/validated across multiple domains/problems

SUMMARY

A bottleneck in efficiently connecting new materials discoveries to established literature has arisen due to an increase in publications. This problem may be addressed by using named entity recognition (NER) to extract structured summary-level data from unstructured materials science text. We compare the performance of four NER models on three materials science datasets. The four models include a bidirectional long short-term memory (BiLSTM) with materials science knowledge to three variants of a more complex model: one with general knowledge (BERT), one with general scientific knowledge (SciBERT), and one with materials science knowledge (MatBERT). We find that MatBERT performs the best overall. This implies that language models with greater extents of materials science knowledge will perform better on materials science-related tasks. The simpler model even consistently outperforms BERT. Furthermore, the performance gaps grow when the models are given fewer examples of information extraction to learn from. MatBERT’s higher-quality results should accelerate the extraction of structured data from materials science literature.

INTRODUCTION

Recently, the number of publications in the field of materials science has grown exponentially. As a result, it has become increasingly difficult for researchers to follow research progress as it emerges, even within relatively restricted sub-domains. The size of the materials science literature means that even relatively simple questions, such as which material candidates have
previously been studied for a particular application, can be difficult or impossible to comprehensively answer. This has created a need for new, more efficient ways to engage with the literature and extract the relevant information therein.

Natural language processing (NLP), the analysis of unstructured text using computers, provides a natural candidate for such an alternative approach. NLP has successfully been applied to a number of materials science applications and is the topic of several recent investigations in materials informatics.\textsuperscript{2–5} Additionally, work has been done to develop meta-learning strategies for NER.\textsuperscript{4,5} Recently, the advent of transformer ML architectures such as BERT\textsuperscript{7} has revolutionized NLP; leading benchmarks such as GLUE\textsuperscript{10} are now dominated by models utilizing attention-based encoder-decoder architectures called transformers\textsuperscript{11} and perform comparably to humans on some tasks. Transformer models have ushered in a new NLP paradigm where large and general NLP models are “pre-trained” on semi-supervised tasks before being fine-tuned for downstream tasks.\textsuperscript{9,12–17} The pre-training approach allows for task-specific models to be trained using relatively few hand-annotated examples; this is a useful feature for practical applications of NLP bottlenecked by annotation such as scientific tasks that contain technical text and esoteric vocabulary.

Although a single pre-trained model may address multiple NLP tasks (e.g., question answering, named entity recognition, etc.), the success of models with domain-specific pre-training such as BioBERT,\textsuperscript{18} CaseHOLD,\textsuperscript{19} and FinBERT\textsuperscript{20} begs the question: can transformer models be further improved with even more domain-specific pre-training? We hypothesize that the measurable advantages previously shown with domain-specific pre-training—for example, of SciBERT over BERT\textsuperscript{21}—can again be extended to models specific to narrower scientific disciplines such as materials science. Improved domain-specific model performance implies improved ability for automated knowledge extraction from even the most complex and vexing (from the perspective of NLP models) scientific domains. Exploring this problem in-depth presents an opportunity for the collation and synthesis of massive numbers of highly complex scientific publications into otherwise inaccessible structured databases and models for knowledge generation.

In this work, we apply transformer models to the task of named entity recognition (NER)\textsuperscript{22} to extract and label important scientific entities relevant to materials chemistry from unstructured text. A well-trained NER model will be capable of automatically mapping the unstructured text of materials science publications to a queryable database of key terms. Historically, NER has been used to extract information such as names and locations from various articles, though recently it has been employed in the chemical, medical, and materials sciences as well.\textsuperscript{1–4,23–39} For material science, this may include terms that refer to materials and their geometries, properties, syntheses, methods of characterization, and downstream applications. Strongly related work in text mining and language modeling has also been employed in the same fields.\textsuperscript{5,40–60} BERT has additionally found use in biology, medicine, and materials science.\textsuperscript{18,61,62}

Specific to the field of materials science, there have been significant efforts to apply NER to the extraction of materials synthesis recipes, including using BERT.\textsuperscript{2,28,29,57,60} In the past, these have employed a combination of the aforementioned work in the chemical sciences to extract inorganic material entities with syntax trees and lookup tables to extract properties and processing conditions. The recently developed transformer-based models have been shown to offer significant performance improvements on NLP tasks.\textsuperscript{9} This provides an excellent opportunity to evaluate the performance of these new models on NER tasks specific to materials science.

In this work, we apply four different NER models to three different materials science datasets and analyze their performance. The simplest model considered is a bidirectional long short-term memory (BiLSTM) recurrent neural network. The other three models, variants of the popular transformer-based BERT\textsuperscript{BASE} neural network structure,\textsuperscript{4} have identical model structures but use pre-training corpora of varying domain specificity. The considered datasets consist of one general-purpose materials science dataset (referred to as the solid-state dataset) and two topic-specific datasets that respectively focus on doping and gold nanoparticle synthesis. We use the results of NER on these materials science datasets to relate the domain specificity of the pre-training corpus to measurable performance differences in extracting named entities.

Datasets
Here we consider three different NER datasets, chosen to represent a diversity of text sources and problems relevant to materials science; a set of solid-state materials science abstracts with entities of broad interest,\textsuperscript{28} a set of abstracts with inorganic doping information, and a set of methods/results sections relevant to gold nanoparticle synthesis. Each of these is described in detail below. The solid-state dataset is publicly available,\textsuperscript{63} though only the DOIs and annotated entities are available for the other two.\textsuperscript{44}

**Solid-state dataset**

The solid-state dataset discussed in this work consists of 800 annotated abstracts from solid-state materials publications collected using Elsevier’s Scopus/ScienceDirect\textsuperscript{65} and Springer-Nature\textsuperscript{66} APIs as well as web scraping for journals published by the Royal Society of Chemistry\textsuperscript{67} and the Electrochemical Society.\textsuperscript{68} Abstracts are considered relevant if they mention at least one inorganic material and at least one synthesis or characterization method for inorganic materials. The entity labels are chosen to represent a broad domain of materials science knowledge with eight different labeled entity types: inorganic materials (MAT), symmetry/phase labels (SPL), sample descriptors (DSC), material properties (PRO), material applications (APL), synthesis methods (SMT), and characterization methods (CMT). Details of the collection and pre-processing of these abstracts and detailed definitions of the labels are available in Weston et al.\textsuperscript{28}

A condensed example is shown in Figure 1.\textsuperscript{69} This dataset is intended to provide a “catch-all” of relevant information without focusing on any specific facet of solid-state materials. Due to the broad definitions of the entities, the solid-state dataset generally contains more entities per paragraph than the other datasets. Additionally, an inter-annotator agreement of 87.4\% was evaluated utilizing 25 annotations from a second annotator.\textsuperscript{78}

**Doping dataset**

The properties of doped materials used for applications requiring semiconductors are determined by critical pieces of information such as the base material (BASEMAT), the doping agent...
Monoclinic zirconia nanowires were synthesized by chemical vapor decomposition using ZrCl4 powder as a starting material. Based on x-ray diffraction and Raman spectroscopy data, the resulting crystal structure was found to be single crystalline monoclinic zirconia. An Au thin film was pre-depositing on a graphite substrate as a catalyst.

(DOPANT), and quantities associated with the doped material such as the doping density or the charge carrier density (DOPMODQ). The intention of this dataset is to capture the information relevant to the doping of a material and any other relevant quantitative measurements. Abstracts that specifically contain information about doping, i.e., those containing regular expressions matching “dop*” (such as “dopant,” “doped,” and “co-doping”) or “n-type” or “p-type,” were queried from the Mat-scholar database of materials science abstracts. A set of 500 abstracts was randomly sampled from the queried set, from which 455 abstracts were identified by human annotators as relevant to inorganic materials science and were annotated by three annotators.

A condensed example is shown in Figure 2. As opposed to the solid-state and gold nanoparticle dataset, tokens were annotated one sentence at a time (one sample = one sentence). Sentences were annotated only when they contain specific and direct information about the doping of solid-state materials, e.g., “X was doped with Y,” “X:Y,” or “Y doping.” Sentences describing byproducts or targeted properties (e.g., magnetization) without direct reference to a dopant or a host material (e.g., “The layered TiO2 phase did not incorporate the dopant specie and had an anatase structure with measured lattice parameters of a = 3.61Å, c = 9.45Å.”) were not annotated.

Gold nanoparticle dataset
Gold nanoparticles (AuNPs) are used widely in biomedicine (e.g., in vitro diagnostics), semiconductor technology, and cosmetics. Despite the strong reliance of AuNP properties on size and shape, only recently have synthesis methods been able to control AuNP morphology, particularly anisotropic nanorods. This dataset aims to capture AuNP morphologies and descriptions from relevant sections of the full text of AuNP synthesis literature. A single annotator annotated a set of 85 characterization paragraphs from 73 articles on AuNP synthesis.

A condensed example is shown in Figure 3. The entities for the synthesized AuNPs, including noun-based morphological entities (MOR) and adjective-based, descriptive entities (DESs). Entities like “particle” or “AuNP” were annotated as MOR entities, so at least some target could be identified with which to attribute size information in the future since many nanoparticle articles only refer to the particles as the less descriptive “nanoparticle” or “NP.” Note that other aspects such as the dimensions of particles were not included due to very low levels of support for such labels in the original data. This is similar to past work on information extraction from nanomaterial synthesis literature. Furthermore, limiting the number of labels will tend to provide better performance, particularly for smaller datasets.

Methods
Four different models are trained and evaluated on each dataset, including a BiLSTM and three variations of networks using the bidirectional encoder representations from transformers (more specifically, BERT) structure. The three BERT networks considered include BERTBASE (uncased), SciBERT (uncased), and a pre-trained model introduced with this work, MatBERT (uncased). Each model, when given an abstract for a materials science publication in the form of a sequence of tokens, learns to classify each token into pre-defined categories. The token categories correspond to combinations of token position and entity type, i.e., B = MAT, for the beginning token of a material entity. In this way, the NER models described here can be understood as sequence-to-sequence models (Seq2Seq) that transform a sequence of words into a sequence of labels. Unless otherwise specified, for each experiment, 80% of the data was used for training, 10% for validation, and 10% for testing. Sixteen different seeds (integer powers of two from 0 to 15) were used to determine the order of the training data as well as the model weight initialization.

Tokenizers
The Materials Tokenizer was used with the BiLSTM model. First, the tokenization step is carried out using ChemDataExtractor with additional pre-processing to split tokens that are either composed of a number and a unit or an element and a valence state. Processing the tokens then consists of filtering numbers to become < nUm > since they are often not tokenized correctly with ChemDataExtractor, normalizing simple chemical formulas so the order of the elements is standardized, lowercasing tokens with only the first letter capitalized that are not elements or chemical formulas, and removing accents.

BERT models, however, use the WordPiece subword tokenization algorithm, which is very similar to byte-pair encoding.
Sm doping favors the formation of hexagonal phase in the host lattice of ZnS:Sm.

The self-activated luminescence intensity increases with the increase in the amount of Sm doping up to a maximum of 0.2 mol% of dopant.
patterns of Fields. SciBERT was shown to outperform BERT on scientific tasks as a result.

Building on this, we present MatBERT as a BERT model trained using scientific papers specifically from the field of materials science. For training MatBERT, we randomly sampled two million papers, or around 61 million paragraphs, from a corpus mostly consisting of peer-reviewed materials science journal articles. To optimize MatBERT models for materials science terminologies, two WordPiece tokenizers (cased and uncased) were trained using these paragraphs with no additional pre-processing. Following BERT practices, the vocabulary sizes for the tokenizers are both 30,522. After tokenization, paragraphs with fewer than 20 or more than 510 tokens were removed, leaving a pre-training corpus consisting of around 50 million paragraphs (8.8 billion tokens). The two variants were trained using only the MLM task. An AdamW optimizer was used with a weight decay of 0.01 and the learning rate of 5 \times 10^{-5} decayed linearly to zero during five training epochs. A batch size of 192 paragraphs per gradient update step was used. The convergence of the MLM loss versus training steps can be found in the supplemental information. Each model was trained on eight NVIDIA V100 GPUs and took about 1 month to complete. The pre-training code and pre-trained MatBERT model weights are publicly available.

RESULTS

In this section, model performances on the aforementioned datasets are reported along with model performance as a function of dataset size. An input sample consists of an entire paragraph from the dataset. The model classification performances are judged according to their achieved precision, recall, and F1-scores using the “micro” averaging scheme to accurately reflect the class imbalances in the datasets. In all experiments, the set of parameters at the end of an epoch that results in the best validation F1-score are evaluated on the test set. In all experiments, training was carried out for 64 epochs for the BiLSTM model and five epochs for the BERT, SciBERT, and MatBERT models. We reiterate that the only difference between the BERT models considered here is the choice of pre-training corpus.

In Figure 4, the performances of the models on the considered datasets are shown. Each point on the scatterplot depicts the 95% CI (assuming a normal distribution) across 16 seeds for the chosen metric, model, and dataset. The precision is the ratio of correctly predicted entities to all predicted entities, and the recall is the ratio of correctly predicted entities to all true entities. The F1-score is the harmonic mean of the precision and recall.

In Figure 4A, it is shown that the MatBERT and SciBERT models perform better than the BERT and BiLSTM models (within statistical error as shown by the CIs) on the solid-state set as determined by the F1-score. For precision, recall, and F1-score, the MatBERT model performs slightly better than the SciBERT model. Interestingly, although the BERT and BiLSTM

and next sentence prediction (NSP). The MLM task requires that the BERT model predicts missing words in input sequences where 15% of the words are masked. The NSP task requires that given two sequences, the BERT model predicts the likelihood that one follows the other. It has been shown that pre-training on different corpora can lead to different performances. This is of particular interest in technical fields where commonly used words and phrases may not be well-represented or even carry the same meaning in other contexts.

The original BERT model was trained on the BooksCorpus (800 million tokens) and English Wikipedia (2.5 billion tokens). By contrast, SciBERT was trained on 1.14 million scientific papers from Semantic Scholar (3.1 billion tokens) across a variety of fields. SciBERT was shown to outperform BERT on scientific tasks as a result.

For training of the BERT models (MatBERT, SciBERT, and BERT) with CRF output and loss, the pre-trained model parameters were fine-tuned. The model structures as well as the BERT pre-trained parameters were provided by the “transformers” library. The SciBERT pre-trained parameters compatible with this library were acquired using the SciBERT Al-
models achieve very similar F1-scores, there is actually a trade-off between the precision and recall with the models, as the BiLSTM model achieves higher precision, whereas the BERT model achieves higher recall. This means that the BiLSTM model is less susceptible to predicting false positives, while the BERT model is less susceptible to predicting false negatives. The precision and recall are much closer in value for the BERT model than for the BiLSTM model.

Furthermore, in Figure 4B, the same metrics for the doping dataset are shown. Once again, the MatBERT and SciBERT models perform better than the BERT and BiLSTM models. Additionally, the MatBERT model once again demonstrates better performance than the SciBERT model for precision, recall, and F1-score. Compared to the BERT model, the BiLSTM model achieves slightly higher precision (0.71 ± 0.03 versus 0.70 ± 0.02). The respective performances are nearly identical for the recall (0.68 ± 0.03) and F1-score (0.69 ± 0.02). However, the CIs are slightly higher with the BiLSTM model.

Finally, in Figure 4C, the same metrics are once again shown for the gold nanoparticle dataset. The MatBERT model again achieves a higher F1-score than the other models, but for this dataset, the BiLSTM model and the SciBERT model achieve a similar F1-score with the BERT model trailing behind. For the recall, it can be seen that the BERT model performs significantly worse than the other models, with the MatBERT model achieving the best performance followed by the BiLSTM model and then the SciBERT model in turn. For the precision, all of the models perform similarly, with the BiLSTM model actually achieving the best performance, followed by the MatBERT model and then the SciBERT model with the BiLSTM model trailing.

Table 2 shows a heatmap of the entity-wise average F1-scores attained for each model across the datasets. The highest score for each entity is in bold. MatBERT claims the best performance for all entities except for one, DSC, where it only slightly lags behind SciBERT. SciBERT then claims the second-best performance for the rest of the entities aside from DES, which the BiLSTM instead claims. Between the BiLSTM and the original BERT, the BiLSTM generally performs better across the entities, only performing much worse compared to BERT for DOPMODQ, slightly trailing behind BERT for the APL, PRO, SMT, and DOPANT entities and performing much better for the solid-state SPL, doping BASEMAT, DES, and MOR entities. Of particular interest is the very poor score of zero obtained by BERT on the DES entity, which was caused by the failure to predict any entities. Since SciBERT also scored poorly on the DES entity (0.29), with the BiLSTM (0.53) and MatBERT (0.67) models significantly outperforming BERT and SciBERT, this would suggest that the domain-specific pre-training is important to DES entity recognition performance.

Generally, the models tend to consistently perform better or worse on the same entities. All of the models tended to perform the poorest on the doping BASEMAT, DOPMODQ, and DES entities and the best on the DSC and MAT entities. There are some exceptions, however, with BERT performing relatively poorly on the SPL and MOR entities despite very good performances from the other models. The model performances on the DES entity vary much more than on the other entities, with very large performance gaps between the models.

To study the effect of the number of training examples on model performance, we plot learning curves for each model on each dataset in Figure 6. Curating and annotating even modestly sized datasets can entail considerable effort from domain experts in physics, chemistry, and materials science due to the highly technical nature of many publications in those fields. This is in contrast to canonical NER tasks such as CoNLL-2003 (a NER set used in the original BERT publication) that aim to identify less technical entities such as organizations, people, or places. Thus, models that can perform well on small training datasets will be of interest to domain experts looking to create structured technical datasets from text using NER.

In Figure 6, we observe MatBERT and SciBERT exhibiting large performance improvements over BERT at low numbers of training samples, in particular with fewer than 200 samples for the solid-state dataset and with fewer than 50 samples with the gold nanoparticle dataset. The BiLSTM model exhibits the best performance as the training set size approaches zero, but asymptotically approaches a lower limit than the SciBERT and MatBERT models as the number of training points increases. On the solid-state dataset, the larger number of annotated examples allows for BERT to close the gap in F1-score, so the CIs are overlapping at 400 samples and are indistinguishable at 600 samples. As opposed to the SciBERT and MatBERT models, however, BERT does not exceed the BiLSTM performance at any of the training sample intervals for any task. This is not to imply that BERT is approaching the same limit as the BiLSTM; rather, we expect that as the number of training samples is further increased, the general BERT model will exceed or reach the BiLSTM due to its much more complex architecture as seen with the solid-state dataset (though this is less clear for the two smaller datasets). Determining whether adding more NER training data for any one task will outweigh the effects of domain-specific pre-training—that is, whether the general

BERT model will overlap SciBERT or MatBERT—requires further investigation with larger numbers of annotated technical text samples. Generally, we observe that more specific pre-training results in increased performance (by substantial margins, e.g., \(0.05\) micro F1-score improvement of MatBERT over general BERT at 320 solid-state training samples) for BERT-derived models at every training set size, particularly at small training set sizes.

Another contributing factor to the difference in performance is class support (the number of labels in the testing dataset for a given class). Figure 7 illustrates the disparity among entities’ F1-score by class support for each of the three datasets. As expected, classes with higher support generally have higher F1-scores, and classes with low support stratify according to the level of pre-training. We would intuitively expect MatBERT to perform much better on rarely mentioned entities than BERT given its higher exposure to materials-related text during pre-training. This can be readily seen with the DES entity and DopMODQ entity, in which model performances likely suffer from very low support (respectively \(\sim 10\) and \(\sim 20\)). For the DES entity, which has the lowest support, the models pre-trained on materials-related text perform significantly better than those trained on general scientific text or just general text. However, the large degree of stratification among BERT models for entities with higher support is of note. Particularly for the PRO entity (e.g., “Voight-Reuss-Hill average bulk moduli”) with a relatively large level of support (~700 samples), MatBERT and SciBERT both make a substantial \(\sim 0.03\) and \(0.04\) F1-score improvement over BERT. This improvement may imply that highly specialized entities, such as materials science properties that do not appear frequently in general corpora but appear frequently in domain-specific corpora, benefit the most from more specialized pre-training even when there are relatively many samples for fine-tuning. For entities that are more commonly mentioned in general text corpora, such as MOR (e.g., “particles,” “rods,” “spheres”), DopMODQ (e.g., “3%”), and DSC (e.g., “crystalline,” “amorphous,” “powder”), the level of pre-training appears less important at every level of support.

DISCUSSION

Whether domain-specific pre-training is needed for large transformer models remains an open question in the field of NLP. Although large models trained on massive general-purpose corpora are complex enough to allow for fine-tuning for various downstream tasks (question/answer, NSP, NER) as opposed to expensive from-scratch retraining, our results show evidence that domain-specific pre-training can measurably improve F1-score performance in the domain of materials science. The overall best performance of MatBERT across the three materials science datasets corroborates a growing body of evidence that domain-specific pre-training is not only a trivial improvement over generally pre-trained models but is indeed worth the effort of retraining large models like BERT. For instance, BioBERT demonstrated as much as 2.8% F1-score improvement over...
BERT in the biomedical domain; similarly, both CaseHOLD\textsuperscript{19} (legal corpora) and FinBERT\textsuperscript{20} (financial corpora) yield improvements over base BERT in their respective domains’ downstream tasks. The word distribution shift from a general-purpose corpus to an exclusively technical corpus is large enough to encourage full retraining of large transformer models.

Our results now introduce the question: How specialized should a pre-training corpus be so that it is both highly performant within a domain of knowledge and general enough to address a variety of NER problems within that domain? Although MatBERT improves on BiLSTM, SciBERT, and BERT for all but the smallest training set sizes, the MatBERT model we introduce is limited by the distribution of pre-training data. As detailed in methods, pre-training data were taken from a general material science corpus.\textsuperscript{2} However, as shown by the most frequent title keywords in Figure 8, this corpus is designed to be biased toward trending materials science topics describing experimental syntheses. For example, paragraphs from full texts tend to favor popular compounds (such as oxides, energy materials, and magnetic materials) or synthesis techniques (such as conventional solid-state or hydrothermal synthesis). The MatBERT pre-training corpus, therefore, puts less weight on computational papers containing density functional theory results, theoretical but yet-to-be-synthesized stoichiometries, and unusual but important phase labels. Thus, MatBERT may be improved by expanding the pre-training corpus beyond the set compiled in Kononova et al.\textsuperscript{2} The goal in selecting a pre-training corpus should be to strike a balance between the specificity needed to capture particular facets of materials science and transferability between disparate fields within materials science. Exploring other methods to sample the materials science literature for the purposes of model training is one possible avenue for future work.

**Conclusions**

As seen in the presented results and ensuing discussion, the MatBERT model achieves the best overall performance out of the considered models. The 1%–4% F1-score improvement over SciBERT demonstrates that domain-specific pre-training provides a measurable advantage for NER in materials science. Furthermore, SciBERT improving upon BERT by 3%–9%
F1-score reinforces the importance of scientific pre-training in general for materials science text. Interestingly, it was even found that a comparatively simple BiLSTM model enhanced with embeddings pre-trained on materials science text provides better overall performance than the original BERT model. This suggests that pre-training on a domain-specific corpus can be more impactful on performance than employing modern large transformer-based models. Learning curves additionally show that in the low data limit, the BiLSTM outperforms the BERT models, albeit still with poor overall performance due to the lack of data. For larger datasets, though, MatBERT provides a definitive improvement in NER predictions that can be expected to accelerate the construction of structured materials science datasets.

**EXPERIMENTAL PROCEDURES**

**Resource availability**

**Lead contact**

Requests for additional information should be directed to the lead contact, Nicholas Walker (walkernr@lbl.gov).

**Materials availability**

This study did not generate physical materials.

**Data and code availability**

The pre-trained MatBERT model as well as the trained MatBERT NER models are publicly at https://figshare.com/articles/software/MatBERT-NER_models/15087276. The code used to pre-train MatBERT is publicly available at https://github.com/lbnlp/MatBERT. The code used to train MatBERT NER is publicly available at https://github.com/CederGroupHub/MatBERT_NER. The DOIs of the articles used for the new datasets alongside the associated extracted entities are publicly available at NER Datasets: https://figshare.com/articles/dataset/NER_Datasets_DOIs_and_Entities_Doping_and_AuNP_/16864357.

**SUPPLEMENTAL INFORMATION**

This work was funded by Toyota Research Institute through the Accelerated Materials Design and Discovery program. Secondary funding to develop the gold nanoparticle dataset as well as MatBERT pre-training was provided for this work by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division under Contract No. DE-AC02-05CH11231 (DOE program KCD2S2). This research used resources of the National Energy Research Scientific Computing Center (NERSC), a U.S. Department of Energy Office of Science User Facility operated under Contract No. DE-AC02-05CH11231. This work also used the Extreme Science and Engineering Discovery Environment (XSEDE) GPU resources, specifically the Bridges-2 supercomputer at the Pittsburgh Supercomputing Center, through allocation TG-DMR9700083.

**AUTHOR CONTRIBUTIONS**

A.J., G.C., and K.A.P. supervised the research. J.D. wrote the data collection infrastructure and performed the data collection. S.L., N.W., A.D., and J.D. annotated the doping dataset. K.C. annotated the gold nanoparticle dataset. H.H. wrote the MatBERT pre-training code and performed the pre-training. N.W., A.T., K.C., S.L., and A.D. wrote the MatBERT NER training code. N.W. wrote the BiLSTM NER training code. N.W. performed the NER experiments and prepared the results. N.W., A.D., and H.H. prepared the figures. All authors contributed to the discussion and writing of the manuscript.

**DECLARATION OF INTERESTS**

The authors declare no competing interests.
