Introduction. Cleidocranial dysplasia (CCD) is an inherited disease caused by mutations in the RUNX2 gene on chromosome 6p21. This pathology, autosomal dominant or caused by a spontaneous genetic mutation, is present in one in one million individuals, with complete penetrance and widely variable expressivity. Aim. To identify the incidence of these clinical findings in the report of the literature by means of PubMed interface from 2002 to 2015, with the related keywords. The report of local patients presents a clinical example, related to the therapeutic approach. Results and Discussions. The PubMed research resulted in 122 articles. All the typical signs were reported in all presented cases. The maxilla was hypoplastic in 94% of the patients. Missing of permanent teeth was found in two cases: one case presented a class II jaw relationship, instead of class III malocclusion. Similar findings were present in our cohort. Conclusion. CCD is challenging for both the dental team and the patient. The treatment requires a multidisciplinary approach. Further studies are required to better understand the cause of this disease. According to this review, a multistep approach enhances the possibilities to achieve the recovery of the most possible number of teeth, as such to obtain a good occlusion and a better aesthetic.

1. Introduction

Cleidocranial dysplasia (CCD) was first described by Pierre Marie and Paul Sainton in 1898 as “dysostose cléido-crânienne héréditaire,” mutational dystosis, or cleidocranial dystosis. Though the first description of cleidocranial dystosis is credited to Meckle in 1760, the combination of clavicular and cranial defects was identified by Scheuthauer in 1871.

CCD is an autosomal dominant inherited disease caused by mutations in the RUNX2 gene on chromosome 6p21 encoding a transcription factor involved in osteoblast differentiation and skeletal morphogenesis. This pathology is transmitted as an autosomal dominant trait or it is caused by a spontaneous genetic mutation and is present at a frequency of one in one million individuals. It presents complete penetrance and widely variable expressivity.

The term “cleidocranial dysostosis” has been used; however, the syndrome got renamed aptly from cleidocranial dystostosis to cleidocranial dysplasia after the conference for constitutional disorders of bone held in Paris in 1969, given that RUNX2 has important functions both during skeletal formation and in bone maintenance, and CCD is affecting not only the clavicles and the skull but the entire skeleton [1, 2]. This rare disease is classified as #119600. A number sign (#) is used with this entry because of evidence that CCD is caused by heterozygous loss-of-function mutation in the RUNX2 gene (600211), encoding transcription factor CBFA1. Heterozygous duplication in RUNX2 resulting in a gain of function causes metaphyseal dysplasia and maxillary hypoplasia with or without brachydactyly (MDMHB; 156510). Pycnodysostosis (265800) and mandibuloacral dysplasia (248370) are disorders to be considered in the
differential diagnosis of CCD. Acroosteolysis and bone sclerosis with tendency to fracture are differentiating features of pycnodysostosis.

Many case reports and case studies have been reported in the literature [3–7]. One of the most colorful families was described by Jackson [8]. The condition occurred in many descendants of a Chinese man named Arnold who embraced the Mohammedan religion and 7 wives in South Africa. Jackson in 1951 was able to trace 356 descendants, of whom 70 were affected by the “Arnold head” [8, 9].

Due to the wide variability, diagnosis solely based on the clinical features may be difficult. CCD is mainly characterized by a pathognomonic deformity of the skull (persistently open skull sutures with bulging calvaria), hypoplastic midface, lack of eruption of permanent teeth, supernumerary teeth, hypoplastic or aplastic clavicles, and multiple other malformations [10]. CCD makes also a special problem for the dentists due to a large number of abnormalities: highly arched palate, cleft palate, delayed union of mandibular symphysis, delayed tooth eruption, dental root and crown abnormalities, crypt formation around impacted teeth, and ectopic teeth. Dental abnormalities are sometimes a sole clinical sign of the mutation.

Early diagnosis of CCD is essential for introduction of an appropriate treatment approach based on interdisciplinary cooperation between orthodontists as well as oral and maxillofacial surgeons and general dentists at the right moment [11].

The main clinical features of CCD include persistently open skull sutures with bulging calvaria, hypoplasia, or aplasia of the clavicles permitting abnormal facility in opposing the shoulders, wide pubic symphysis, short middle phalanx of the fifth fingers, dental abnormalities, and often vertebral malformation (Table 1).

Cooper et al. in 2001 assembled a series of 90 CCD individuals and 56 relative controls ascertained from genetic and dental practices in the United States, Canada, Europe, and Australia. A number of previously unrecognized complications were significantly increased, including scoliosis, pes planus, sinus infections, upper respiratory complications, recurrent otitis media, and hearing loss [12].

Dental abnormalities, including supernumerary teeth, failure of exfoliation of the primary dentition, and malocclusion, were found to be serious and complex problems that required intervention. The combination of normal deciduous teeth, delayed eruption of permanent teeth, and multiple impacted supernumerary teeth is practically diagnostic of CCD.

The increase in odontogenesis leads to excessive number of supernumerary teeth. A study by Yamamota et al. concluded that an early loss of gubernacular cords resulted in failure of a tooth to erupt [13].

As stated by Roberts et al. in 2013, “the supernumerary teeth in CCD may result from the lack of inhibition or incomplete resorption of tooth bud formation. Supernumerary teeth may also result from the presence of remnants of dental laminae following dental extraction. These epithelial cell rests are usually resorbed during the normal tooth morphogenesis” [9].

It has been argued that CBFA1 mutations segregate with the CCD phenotype and that heterozygous loss of function is sufficient to produce the characteristic clinical findings. The CBFA1, a subunit of the core binding factor (CBF) transcription factors, probably plays a significant role in bone development, as it has been revealed by mutated mice in which the Cbfal was completely deficient and died immediately after birth owing to a complete absence of bone. The cause was identified in an arrest in endochondral as well as membranous bone formation. Moreover, the stimulation of cells that normally do not express Cbfal with BMP7 (a secreted molecule that can induce bone formation) leads to expression of Cbfal before the expression of any other osteoblast marker genes identifying Cbfal as an inducer of osteoblast differentiation (Figure 1).

Very recent findings suggest that Cbfal is not only essential for osteoblast formation, but also a major regulator of chondrocyte differentiation. In Cbfal (−/−) mice chondrocytes, hypertrophy within this cartilaginous model does not take place, indicating a role for Cbfal. In addition, also vascular invasion of calcified cartilage does not take place [12].

Throughout the years, different clinical approaches for the treatment of patients with CCD have been suggested in the literature [13, 14].

1) The Toronto-Melbourne approach is based on timed, serial extractions of deciduous teeth; it depends on the extent to which the roots of the permanent teeth have developed, so for this approach, the best period for treatment is in the initial stages with a combined oral surgery and orthodontic approach. It is recommended that surgical procedures should begin at about 5 to 6 years of age with extraction of the anterior deciduous teeth (Table 2). Later (6 or 7 years of age), the deciduous incisors are exposed, and healing is allowed; orthodontic brackets are placed on the permanent incisors as soon as possible, and the deciduous posterior teeth are extracted. When the patient is 9 or 10 years of age, the permanent premolars are exposed and allowed to heal. Thereafter, orthodontic brackets are placed on the permanent canines and premolars. During each procedure, which is performed under general anesthesia, the supernumerary teeth are also removed together with the bone covering the underlying permanent teeth.

2) The Belfast-Hamburg approach is a single surgical approach that limits the number of surgeries to a single episode. All deciduous and supernumerary teeth are extracted, and all unerupted permanent teeth are exposed simultaneously under general anesthesia. Surgical packing is placed, and healing occurs by secondary intention. The surgical packs are changed frequently until brackets can be bonded into place. Orthodontic appliances are placed on the few fully erupted teeth, and elastics are tied to the unerupted teeth to encourage eruption (Table 3).
N—the Jerusalem approach is based on at least 2 surgical interventions, depending on the root development of the permanent dentition. In the first phase, which begins approximately at 10 to 12 years of age, the anterior teeth are involved in the treatment in phase 2 (age 13 years and older), and the posterior teeth are treated. These stages are carried out simultaneously in both jaws under general anesthesia. One of the goals of this approach is to immediately deal with the absence of anterior teeth by placing an orthodontic appliance to erupt the anterior teeth first (Table 4).

(4) The “Bronx Approach” uses an interim overdenture prosthesis during the long course of treatment [15]. The timing of the surgical intervention is dependent on the root development of the permanent teeth (Table 5).

1.1. Aim of the Study. The aim of the study is to identify the incidence of delayed eruption of permanent teeth and other dentoalveolar findings, that is, supernumerary teeth, eruption failure, and hypoplastic upper jaw, on all clinical reports found on international literature by means of PubMed interface form January 2002 to December 2015. We investigated the incidence of high-arch palate and contraction of the upper jaw and the response to dentoalveolar or skeletal expansion using orthodontic appliances, such as TPA, Quad-helix, or REP. A local patient cohort with a family report of three patients has been analyzed, identifying most suitable treatment strategy.
2. Materials and Methods

The study is divided into two sections: a systematic review of the literature and the description of a family of two patients and their mother with CCD observed in our Department of Orthodontics of “Sapienza”-University of Roma.

2.1. Literature Review (LR)

2.1.1. Inclusion and Exclusion Criteria. All case series and case reports on humans reporting description of clinical parameters in CCD-affected patients were included from January 2002 until December 2015. Grey literature was excluded. Only reports written in English, German, or French were included.

Papers that were primarily concerned with specific pathological findings or radiological modalities were not included. All reports that contained only genotype descriptions were excluded. Studies about prenatal diagnosis of CCD were not included in the LR.

2.1.2. Search Strategy. The PubMed interface of Medline (http://www.ncbi.nlm.nih.gov) was searched using the following keywords: “Cleidocranial dysplasia,” “Dysostose cléido-crânienne,” “Cleidocranial dysostosis,” and “Osteodontal dysplasia.”

The cases presented include literature reference, gender distribution, and patients’ age at the time of presentation. Signs and symptoms were divided into the categories “supernumerary teeth,” “failure of tooth eruption,” “delayed eruption of permanent teeth,” “hypoplastic maxilla,” “transversal contraction of the maxilla,” “clavicular sign,” and “other skeletal disorders.” As described in the literature, the “clavicular sign” was defined by the patient’s ability to oppose the shoulders in front as a result of hypoplastic or aplastic clavicles. The family history was also considered.

Furthermore, the aim was to investigate the answer of these patients to an orthopedic therapy using the rapid palate expander (REP), hypothesizing that most patients do not have a positive response to the device, needing surgical-assisted rapid palate expansion (SARPE) to correct the transversal discrepancies.

2.1.3. Local Patient Cohort. The clinical features of two siblings and their mother, all affected by CCD, who came to our department of Orthodontics at Sapienza University of Rome are described. The patients came to our observation after being treated by a general dentist without any successful therapy. Orthopantomographic and lateral cephalometric radiographs were prescribed as well as a TC cone-beam to evaluate dental and skeletal conditions. Moreover, a detailed anamnesis was collected to evidence the pedigree of the family. All medical files were also considered to picture a precise diagnosis of the two patients, including the growth stage and prediction to elaborate an accurate treatment planning.

This study was approved by the Department of Oral and Maxillofacial Sciences—Umberto I Hospital IRB, and all participants signed an informed consent agreement.
3. Results

3.1. Genetics of CCD. Runx2 is part of a transcription factor complex that directs the differentiation of mesenchymal precursor cells toward mature osteoblasts. Mutations of R225 are most frequently identified with many independent CCD patients reported to date. R225 resides within a stretch of basic amino acids at the carboxy terminus of the runt domain. This motif has been shown to act as a nuclear localization signal, and mutations affecting R225 inhibit the nuclear accumulation of Runx2 protein [14, 16].

Runx2 is expressed in an initial period of embryonic development; it plays a significant role in both chondrocyte and osteoblast lineages. Osteoblasts take part in new bone formation.

RUNX2 plays a significant role in the epithelial-mesenchymal interactions that control progressive tooth morphogenesis and histodifferentiation of the epithelial enamel organ.

4. Literature Review

The PubMed research resulted in 122 articles containing the keywords “Cleidocranial dysplasia,” “Dysostose cléido-crânienne,” “Cleidocranial dysostosis,” and “Osteo-dental dysplasia.” Among these 122 articles, 42 were excluded from the SR only by reading the title and the abstract, as they treated the following:

(i) Prenatal diagnosis of CCD (6 articles)
(ii) Neonates with CCD (4 articles)
(iii) Nonsyndromic conditions of patients presenting supernumerary teeth (8 articles)
(iv) Related syndromes presenting similar symptoms as CCD such as Yunis-Varón Syndrome OMIM #216340 (6 articles), Ehlers Danlos syndrome OMIM #130000, Pycnodysostosis OMIM #265800 (2 articles), anophthalmia syndrome OMIM #206900 (1 article) other genetic mutations (4 articles)
(v) A cover picture was excluded from the LR
(vi) A quiz was also excluded from the LR
(vii) No full text available (9 papers).

After careful analysis of the remaining 80 full texts, it was possible to exclude further 23 papers for several reasons. Table 6 shows the articles excluded and the rationale for exclusion.

Three papers were specifically researched on the PubMed interface and included in the LR as perfectly matching the inclusion criteria. Finally, 60 were included in the SR as they reported the variables of interest (Table 7) (Figure 2).

Of all the variables reported, we analyzed those relative to the clinical signs of the syndrome and those related to the kind of treatment performed.

Among all the case reports analyzed, we can subdivide our population in two groups on the basis of gender (Table 8). The first group consists of 46 female patients with a mean age of 18.85 years. Supernumerary teeth were reported in all presented cases. There was an eruption failure and delayed eruption of permanent teeth in all cases as well. The maxilla was hypoplastic in 94% of the patients. Maxillary contraction and the clavicular sign were found in all the cases reported. Missing of permanent teeth was found in two cases: tooth 3.2 in one case and tooth 3.7 in the other case were missing.

Four patients were treated with orthognathic surgery for maxillary advancement. The contraction of the upper jaw

was treated with different orthodontic appliances: REP, Hyrax, transpalatal arch (TPA), and removable appliance (Schwartz appliance) followed by Delaire mask. All answered positively to orthodontic therapy (Table 9).

The second group consists of 33 males, mean age 18 years. All presented supernumerary teeth, eruption failure, delayed eruption of permanent teeth, maxillary contraction, and the clavicular sign. The maxillary contraction was treated in one case with crisscross elastics and in two cases with a TPA. Of these patients, 94% had hypoplastic maxilla; one case presented a class II jaw relationship, whereas all the others had a class III malocclusion. Two patients underwent orthognathic surgery for maxillary advancement and mandibular setback (Table 10).

4.1. Family Report. A family of three subjects, a mother and two siblings, has been analyzed in all the details of the clinical findings. A complete examination, both for the oral characteristics and for the general relevant data,
is reported. For each case, a possible treatment plane has been hypothesized following the three therapeutic approaches illustrated above.

4.1.1. Case 1. A 12-year-old boy, S. R., came to an evaluation in October 2015 in the Orthodontic Department of Sapienza University of Rome. His weight was 24 kg (<3 centile) and height was 1.20 m (<3 centile), born from cesarean delivery at 39 weeks to a mother affected by CCD. He presented open fontanels and patent sutures at birth. Closure of anterior fontanel occurred at 3 years of age. In 2016, he underwent a complete clinical and auxological evaluation at the Department of Rare diseases of Sapienza University of Rome. His weight was 21.5 kg (25 centile) and height was 118.5 cm (25 centile), and the hand-wrist X-ray showed skeletal age of 6 years. Clinical examination showed narrow clavicles and accentuated joint mobility. The patient can oppose the shoulders on the midline. Orthopedic assessment showed left lumbar scoliosis and right dorsal scoliosis.

Audiological examination: normal audiometry and impedidentiometry with tympanogram type A on the right and type C on the left. The cocleostapedial reflex was present bilaterally for both ipsilateral and contralateral stimulations.

Laboratory findings: deficit of vitamin D 25-OH (17.5 ng/ml), Beta-Cross Laps levels of 0.81 ng/ml. DEXA z-score -2.8.

X-Ray of the spine (2 projections) and long bones (2 projections) shows pseudarthrosis of the medial third of both clavicles, that appears hypoplastic. Iliac wings appear squared and narrow. Hypoplastic pubic bones. Valgus femoral necks. Widened cephalic nuclei of the femoral bone. Proximal pseudoepiphysis of the second and fifth metacarpis in both hands. Brachy-telefalangy with hypoplastic nails. Retarded skeletal age between 6 and 7 years. TC of the head: mastoid appear thickened and narrow. Narrow antral cavities with thickened walls. Tympanic cavities with thickened walls. Cochlea surrounded by compact dense bone. Hyperemia of presphenoidal adenolymphoid tissues. Deviation of nasal septum.

The orthodontic diagnosis is summarized in Table 11 (Figures 3–8).

4.1.2. Treatment Planning. We will proceed using a two-stage approach, like a "Jerusalem approach" to provide:

(i) Aesthetic for the patient in the frontal area because the time for eruption of the incisors is passed since

| Table 11: Case 1: orthodontic diagnosis summary. |
| --- | --- | --- |
| Facial and functional findings | Dental findings | Skeletal findings |
| Brachyfacial | Mixed dentition: All deciduous teeth except 3.1 and 1.6, 2.6, 3.6 and 4.6 | U-shaped upper and lower arches |
| Concave profile | 5 supernumerary teeth in the upper jaw | Class I skeletal relationship |
| Normotonic facial muscles | Class I molar relationship, class I canine deciduous relationship | Reduced width of anterior cranial base |
| Mouth breathing | Median lines are not coincident, the inferior is deviated on the right | Reduced total divergency |
| Atypical swallowing | Overjet reduced | Anterior rotation of maxilla |
| Normal insertion of labial and lingual frenulum | Overbite reduced | Counterclockwise rotational growth |
| | | Endoinclined lower incisors |

Figure 3: Case 1: pretreatment facial photographs.
several years (although the patients shows delayed eruption of teeth and growth), it’s important to exploit the residual *vis a tergo* of these teeth because the canines have the longest and most tortuous path of eruption, and they are located much higher than the crowns of the incisors. To provide this orthodontic approach firstly, the patient will require a skeletal expansion of the upper jaw. A Rapid palatal expander will be designed with bands on 1.6 and 2.6, rests on 5.4 and 6.4, with several arms and loops for the

**Figure 4:** Case 1: intraoral photographs.

**Figure 5:** Study casts.
orthodontic traction of the central and lateral upper incisors.

After extraction of deciduous and supernumerary teeth of the anterior upper area, under general anesthesia, the 4 upper permanent incisors will be exposed and immediately bonded for traction under a closed flap. On the lower jaw, he will also need extraction of deciduous teeth. A lingual arch with rests on deciduous first molars and loops for the orthodontic traction of the lower incisors will be employed.

(ii) Only after disinclusion of all incisors, and after surgical removal of deciduous and supernumerary teeth, we will proceed with the lateral sectors, probably using an intraoral double arch, like the arch used with the Delaire mask, but provided of arms for the traction of canines.

4.1.3. Case 2. The patient S.A., older sister of the first patient, came to the orthodontic Department of the University “Sapienza” of Roma in October 2015 at the age of 17, with weight 62 kg and height 1.57 m. Born from caesarian delivery at 37 weeks from mother affected by CCD. She underwent cataract surgery at two years. At the age of 3 years she underwent genetic counseling. X-Ray of the thorax showed missing ossification of median third of right clavicle; normal left clavicle. X-Ray of the skull evidenced Wormian bones. At 5 years of age she underwent adenotonsillectomy.
Hypertrophy of turbinates remains. In 2014 another clinical assessment shows overweight (65 kg), short stature (1.52 m), discrete joint laxity, pes planus, genu valgus.

Audiological examination: normal audiometry and impedance with tympanogram type A on the right and type C on the left. N–he cocleostapedial reflex was present bilaterally for both ipsilateral and contralateral stimulations. No alteration was evident on the TC scan of the middle ear.

1) Laboratory findings: deficit of vitamin D 25-OH (19 ng/ml).

Orthopedic examination in 2015 shows left lumbar scoliosis, dorsal kyphosis, and bilateral scapula humeral anteverision, greater on the right. Bilateral genu valgus recurred. Pes planus valgus, flexible not painful, are also present.

X-ray of the spine (2 projections) and long bones (2 projections) shows convex dorsal left scoliosis with modest accentuation of dorsal kyphosis. Pseudarthrosis of the medial third of right clavicle. Slight hypoplastic left clavicle. Cervicocephalic valgism of both femoral necks. Slight curving of median third of both tibial diaphysis of the tibiofemoral joints.

DENT A Z-score ~2.8. Skeletal age of 15-16 years.

The orthodontic diagnosis is summarized in Table 12 (Figures 9–14).

4.1.4. Treatment Planning. In this case, a single surgical stage approach was chosen, similar to the “Belfast–Hamburg” approach. The treatment will be performed using a double intraoral arch welded on bands on 16 and 26, provided of multiloops on both palatal and vestibular arch and secured with two mini-screws.

“Temporary anchorage devices” (TADs) inserted on the comfort zone of the palate aimed to provide orthodontic traction of 12, 11, and 22 in first place and afterwards canines and bicuspids.

Moreover, we want to use a double intraoral arch for the lower jaw as well. This will be provided of power arms to secure it by means of TADs placed on the vestibular mandibular cortical. All the teeth to be disimpacted will be bonded as possible in the same surgical phase.

4.1.5. Case 3. The mother of the siblings, P.F. 44 years old, weight 86 kg and height 1.54 m is also affected by CCD. She was born in podalic position by vaginal delivery and weighted

2,100 g at birth. She is allergic to Nichel and lanolin alcohol and presents a kidney with double calyx. She underwent surgery 4 times for kidney stones and one time for debridement of temporomandibular joint. When she was 15, she extracted supernumerary teeth and deciduous molars from the III quadrant of the mouth. Until the age of 30 years, she had only lost the four lower incisors and for the rest, was in deciduous dentition. In 2000, she began several surgeries for the extraction of deciduous teeth and supernumerary in the remaining quadrants. She reports to have until 3 supernumeraries for tooth. Finally, she underwent orthognathic surgery for advancement and expansion of the upper maxilla.

In 2014, she is sent by the Department of Maxillofacial Surgery to the Department of “Rare diseases” to assess a complete picture of the clinical and radiological situation before planning a mandibular setback for the resolution of the anterior crossbite. At the CT scan of the head, previously realized, important sclerosis of the cranial vault, with thickening of the interior and exterior planking, was visible: patent sutures and fontanels; important sclerosis of the cranial base, on the petrous part of the temporal bone; poor gasification of antral cavities and mastoids; deviated nasal septum; slight hypertelorism. X-ray of the spine (2 projections) and long bones (2 projections) shows hypoplastic clavicles with pseudoarthrosis of the median third: hypoplastic scapulae and glenoid fossae; small iliac wings; widened sacroiliac synchondrosis with sclerotic processes on the articular surfaces; thickened cortical of the femoral diaphysis; tibiofemoral valgism.

Laboratory findings show deficit of vitamin D (25(OH) D, 18.1 ng/mL), low levels of phosphates, and elevated level of PTH. The DXA showed a Z-score of −1.4 at the lumbar spine and −0.5 at the left hip. The pedigree of the family shows how the mutation did not skip any generation; this finding strongly points out an autosomal dominant inheritance pattern, characterized by the 50% risk of affected offspring. The mother of the grandfather and grandfather himself were affected by CCD (Figure 15). The patient is not sure yet if she wants to start a new treatment course and refused to realize the lateral Teleradiography because of the numerous previous unsuccessful interventions she underwent and the poor aesthetic results she obtained until today. For this reason, only the clinical, photographic, and plaster model findings were available.

The orthodontic diagnosis is summarized in Table 13 (Figure 16–18).

### Table 12: Case 2: orthodontic diagnosis summary.

| Facial and functional findings | Dental findings | Skeletal findings |
|-------------------------------|----------------|------------------|
| Brachycephalic                 | Mixed dentition with presence of 16, 17, 21, 26, 27, 31, 36, 37, 41, 46, 47 | Contraction of upper jaw |
| Concave profile with prognathic chin | 6 supernumerary teeth in the maxilla and 5 in the lower jaw | Class III skeletal relationship |
| Normotonic facial muscles and masticatory muscles | Class III molar relationship bilaterally | Reduced width of anterior cranial base |
| Nasal breathing                | Class III deciduous canine relationship on the left (lower canine is missing on the right) | Reduced divergence (SN/ML) 16° |
| Normal swallowing             | Centered dental midlines | Anterior rotation of maxilla |
| Normal insertion of labial and lingual frenulum | Overjet reduced | Counterclockwise rotation of maxilla and mandible |
|                               | Overbite reduced | Endoinclined lower incisors, proclined upper incisors with normal interincisor angle |

![Figure 9: Case 1: pretreatment facial photographs.](image-url)
Figure 10: Case 1: intraoral photographs.

Figure 11: Study casts.
teeth. It is advisable to extract all the supernumerary teeth and of the impacted lower canines, due to their low horizontal position. The alignment and orthodontic traction of the impacted 1.3 will be realized, and the arches will be prepared for a subsequent orthognathic surgery of maxillary advancement and mandibular setback. The extraction of the impacted posterior molars will be realized in that occasion. A complete treatment of the gingivitis will...
precede all the orthodontic and surgical phases. A restorative reconstruction of the damaged elements will follow the complete orthodontic and surgical procedures.

5. Discussion

This report reviews 79 patients with CCD excluding all children under the age of 2 years and over 60. The presence of dental signs such as supernumerary teeth, delayed eruption of permanent teeth, and eruption failure are almost constant in all patients. The family we observed at our Orthodontic Department shows all these dental findings. Such high percentage of dental problems underlines the importance of early diagnosis and multidisciplinary treatment for more reasons.

(1) The surgical and orthodontic techniques involved in the dental management of this condition are demanding at the levels of diagnosis, treatment planning, and clinical management. Thus, to achieve the best possible result, the highest degrees of orthodontic and surgical cooperation are necessary.

(2) Starting the treatment early with so many surgical procedures can be challenging for a young child but offers the advantage that the patient will have restored function and esthetics in adolescence, which can be psychologically important [9].

(3) The natural eruption of teeth with roots should be allowed after the removal of obstacles, such as deciduous or supernumerary teeth.

(4) The lack of eruption in patients with CCD is due to failure of resorption of the overlying alveolar bone. When these teeth are uncovered, they show a normal eruption pattern. There can also be mechanical interference from impacted supernumerary teeth.

(5) Moreover, sagittal deficiency of the upper jaw was investigated. This characteristic of the skull was found in almost all patients reported.

Some peculiarities are seen in the cephalometric measurements of a patient with CCD. Because the base of the skull is smaller than in patients who do not have the syndrome, measurements such as SNA, SNB, and facial angles appear greatly increased compared with normal ones. In addition, CCD is usually seen in a brachycephalic patient with horizontal growth, expressed by diminished measurements such as the y-axis, FMA, and SN/GoGn [9].

The familiar group with cleidocranial dysplasia, studied in the second part of our study, shows most of the characteristics found in the literature. At the cephalometric examination of our patients, both showed reduced width of the anterior cranial base. The sister has a skeletal class III jaw relationship, according to both ANB and AOBO, which we aim at correcting with Le Fort I advancement of the maxilla at the end of presurgical orthodontic treatment. The mother already underwent a maxillary surgical-assisted expansion, but still requires presurgical orthodontic treatment, extraction of supernumerary teeth, and Figure 13: Cephalometric analysis.
BSSO surgery for mandibular setback and correction of the anterior crossbite.

The younger son is now in Class I relationship and presents a marked failure to thrive. The mandibular bone growth continues in boys even after completion of statural growth according to the growth curves of Björk [97].

Sagittal jaw relationship will be monitored during the following years, but the correction of the transversal

Figure 14: TC dentascan of both arches.

Figure 15: Pedigree of the family affected by CCD.
discrepancy and forced orthodontic eruption of upper and lower incisors are the main concern at this time point.

The reports of literature described various appliances (REP, TPA, and HYRAX) for the transversal correction, and none reported a failure of such procedure.

Finally, it is important to underline the importance of bone anchorage for the orthodontic traction of the impacted teeth. Skeletal anchorage in orthodontics as absolute anchorage provides new opportunity to guide impacted teeth into occlusion and to treat patients with CCD, making it possible to induce eruption simultaneously of the maxillary and mandibular teeth and consequently reducing patients’ treatment times and psychological stress [98].

This is our aim in the treatment of the older sister: secure two double-arch wires by fixing them to the median or paramedian anterior palate using two mini-screws in the upper jaw and to the inter-radicular septum of the dentulous alveolar process in the mandible. This will provide maximum anchorage for the forced eruption of impacted teeth, without affecting the only permanent teeth present now (upper and lower first and second molars).

6. Conclusion

Revision of the literature is vital for the treatment planning of difficult cases, such as individuals affected by rare diseases, which involve numerous aspects of oral health; CCD is challenging for both the dental team and the patient. The treatment requires a multidisciplinary approach and a strong compliance through many years. A treatment of such condition can last years. It is very important to constantly motivate the patient to full compliance and to keep a scrupulous oral hygiene to avoid the risks that come with orthodontic treatment.

Further studies are required to better understand the cause of delayed eruption of permanent teeth and the abnormal presence of numerous supernumerary teeth that interfere with normal shading of primary dentition.

With the advancement of orthodontic techniques, together with the use of cone-beam for better understanding of the patients’ dental situation and the TADs for skeletal anchorage, the treatment results will be greater in future.

Table 13: Case 3: orthodontic diagnosis summary.

| Facial and functional findings | Dental findings |
|-------------------------------|-----------------|
| Brachycephalic, symmetric      | Presence of 1.1, 1.2, (1.3 impacted) supernumerary, 1.4, 1.6, 1.7, (1.8 impacted) 2.1, 2.2, 2.3, 2.4, 2.5, 2.6, 2.7, 2.8, (2.9 impacted) 3.1, 3.2, 7.3 (3.3 impacted) 3.4, 3.5, (supernumerary impacted) 3.6, (3.8 impacted), 4.1, 4.2, 4.3 (2 impacted supernumerary) 4.4, 4.5, 4.6, (impacted 4.8). |
| Concave profile with prognathic chin | 6 supernumerary teeth in the maxilla and 5 in the lower jaw |
| Reverse smile arch, with lower incisors exposure | Class III molar relationship bilaterally |
| Not visible keratinized gengiva | Class III canine relationship nonapplicable |
| Normotonic facial muscles and masticatory muscles | Not centered dental midlines |
| Nasal breathing | Overjet: ~0.5 mm; overbite: 0 mm |
| Normal swallowing | Accentuated Spee curve |

Figure 16: Case 3: extraoral pictures.
According to this review, we chose to treat our patients following a multistep approach thus enhancing the possibilities to achieve the recovery of the most possible number of teeth, to obtain a good occlusion and a better aesthetic, especially of the anterior region. The treatment of the adult patient is obviously requiring a multidisciplinary approach due to the need of surgical correction of the sagittal and transversal discrepancies and due to the need of a prosthetic reconstruction of the missing teeth. A strong suggestion of an early diagnosis and an early treatment seem then to be mandatory to improve the prognosis of the cleidocranial-related anomalies.

Conflicts of Interest

The authors declare that they have no conflicts of interest.
