Explore life up to 40°C

NovoEight® (turoctocog alfa) is the only rFVIII with 3 months stability up to 40°C*16

- Not refrigerating FVIII products was associated with greater patient satisfaction and less restriction on daily activities*7

Prescribing Information NovoEight® NovoEight® 250 IU NovoEight® 500 IU NovoEight® 1000 IU NovoEight® 1500 IU NovoEight® 2000 IU NovoEight® 3000 IU Powder and solvent for solution for injection Turoctocog alfa is recombinant coagulation factor VIII (FVIII) produced in Chinese hamster ovary (CHO) cells by recombinant DNA technology. NovoEight® 250 IU contains approximately 0.25 IU/mL, 500 IU contains 0.5 IU/mL, 1000 IU contains 1.0 IU/mL, 1500 IU contains 1.5 IU/mL, 2000 IU contains 2.0 IU/mL and 3000 IU contains 3.0 IU/mL turoctocog alfa after reconstitution. Indication: Treatment and prophylaxis of bleeding episodes in adults and children with haemophilia A. NovoEight® can be used for all age groups. Pharmacology and pharmacokinetics: The dosage and duration of the substitution therapy depend on the severity of the factor VIII deficiency, on the location and extent of the bleeding and the patient’s clinical condition. On demand treatment: Required FVIII = body weight (kg) x desired factor VIII level x % (e.g. plasma FVIII level x 0.8 IU/dL to 1.5 IU/dL, depending on the level of the desired activity). Early haemarthrosis, muscle bleeding or oral bleeding. FVIII level required (IU): 20-40 IU/dL, repeat infusion every 12-24 hours, at least 1 dose. More extensive haemarthroses, muscle bleeding or haemorrhage. FVIII level required (IU): 50-100 IU/dL, repeat infusion every 6-24 hours until resolution is reached. Surgery Minor surgery, including tooth extraction. FVIII level required (IU): 80-120 IU/dL, repeat infusion every 6-24 hours until adequate haemostasis is achieved. Major surgery FVIII level required (IU): 100-150 IU/dL, repeat infusion every 6-24 hours until adequate haemostasis is achieved. Therapy for at least another 7 days to maintain a factor VIII level of 30-60% (80-120 IU/dL). Pregnancy (adults and children above 12 years). The recommended dose is 20-40 IU/kg body weight every second or 20-50 IU/kg body weight 3 times weekly. In adults and adolescents (<12 years) less frequent regimens (40-60 IU/kg every third day or twice weekly) may be applicable. In some cases, especially in younger patients, shorter dosing intervals or higher doses may be appropriate. For patients -- children below 12 years and patients above 12 years in the age above 12, doses of 25-50 IU/kg body weight every second or 25-50 IU/kg body weight 3 times weekly are recommended. Method of administration: Intravenous use. The recommended infusion rate for NovoEight® can be increased by up to 50%. Correction: The preferred correction for NovoEight® is to use an external method of administration, such as an external infusion pump. Therapeutic efficacy: The recommended correction for NovoEight® is to use an external method of administration, such as an external infusion pump. Therapeutic efficacy: The recommended correction for NovoEight® is to use an external method of administration, such as an external infusion pump. **Therapeutic efficacy: The recommended correction for NovoEight® is to use an external method of administration, such as an external infusion pump.**

Summary

The randomized, double-blind, double-dummy, phase 3b RELIEF trial evaluated polycythæmia vera (PV)-related symptoms in patients who were well controlled with a stable dose of hydroxycarbamide (also termed hydroxyurea) but reported PV-related symptoms. Patients were randomized 1:1 to ruxolitinib 10 mg BID (n = 54) or hydroxycarbamide (prerandomization dose/schedule; n = 56); crossover to ruxolitinib was permitted after Week 16. The primary endpoint, ≥50% improvement from baseline in myeloproliferative neoplasm symptom assessment form total symptom score cytokine symptom cluster (TSS-C; sum of tiredness, itching, muscle aches, night sweats, and sweats while awake) at Week 16, was achieved by 43-4% vs. 29-6% of ruxolitinib- and hydroxycarbamide-treated patients, respectively (odds ratio, 1.82; 95% confidence interval, 0.82–4.04; P = 0.139). The primary endpoint was achieved by 34% of a subgroup who maintained their hydroxycarbamide dose from baseline to Weeks 13–16. In a post hoc analysis, the primary endpoint was achieved by more patients with stable screening-to-baseline TSS-C scores (ratio ≤ 2) receiving ruxolitinib than hydroxycarbamide (47% vs. 25%; P = 0.0346). Ruxolitinib treatment after unblinding was associated with continued symptom score improvements. Adverse events were primarily grades 1/2 with no unexpected safety signals. Ruxolitinib was associated with a nonsignificant trend towards improved PV-related symptoms versus hydroxycarbamide, although an unexpectedly large proportion of patients who maintained their hydroxycarbamide dose reported symptom improvement.

Keywords: polycythæmia vera, quality of life, signs and symptoms, Janus kinase, hydroxycarbamide.
Polycythaemia vera (PV) is a Philadelphia-negative myeloproliferative neoplasm (MPN) characterized by primary erythrocytosis and deregulated Janus kinase/signal transducer and activator of transcription signalling (Vannucchi, 2014). Most patients with PV experience a broad symptom burden that may include fatigue/tiredness, itching, muscle aches and sweating (Emanuel et al, 2012; Vannucchi et al, 2015). The biomolecular underpinnings of PV-related symptoms have not been fully elucidated. However, elevated serum inflammatory cytokine levels have been reported in MPN patients (Barbui et al, 2011; Vaidya et al, 2012; Pourcelot et al, 2014) and may contribute to the severity of symptoms, including itching and night sweats (Tefferi et al, 2011; Squires et al, 2013). Other common aspects of the PV disease state, including blood hyperviscosity (Barbui et al, 2013) and splenomegaly (Mesa et al, 2007), may also play a role in the symptom profile of some patients. The overall PV-related symptom burden, as measured by the MPN Symptom Assessment Form total symptom score (MPN-SAF TSS), as well as the severity of individual symptoms, including fatigue (Emanuel et al, 2012; Abelson et al, 2013) and itching (Siegel et al, 2013), have been associated with reduced quality of life in patients with PV.

Polycythaemia vera is adequately managed with phlebotomy and low-dose aspirin in some patients (Marchioli et al, 2013), but many require additional therapy to achieve their treatment goals. The most common cytoreductive treatment is hydroxyurea (HC, also termed hydroxyurea) (Vannucchi, 2014), which is effective for controlling blood cell counts in some patients (Najean & Rain, 1997; Alvarez-Larran et al, 2012). However, PV-related symptoms are generally not well controlled with HC treatment (Johansson et al, 2012; Scherber et al, 2012).

In the phase 3 RESPONSE trial, ruxolitinib treatment was superior to best available therapy for the control of haematocrit without phlebotomy and management of splenomegaly in patients with PV who had an inadequate response to, or were intolerant of, HC (Vannucchi et al, 2015). Ruxolitinib treatment was also associated with improvements in PV-related symptoms (Vannucchi et al, 2015; Mesa et al, 2016). We therefore conducted a randomized, double-dummy, placebo-controlled phase 3b trial (RELIEF) in patients who had receiving a stable dose of HC and were generally well controlled but still reported disease-associated symptoms. The primary objective of the trial was to compare the change in PV-related symptom burden in patients continuing their HC therapy with those switching to ruxolitinib.

Methods

Patients

Eligible patients were ≥18 years of age, diagnosed with PV according to the World Health Organization criteria (Tefferi & Vardiman, 2008), treated with HC monotherapy for ≥12 weeks before enrolment, had received a stable dose of HC for ≥4 weeks before enrolment and had cytokine-related symptoms defined as a score ≥8 (maximum, 50) on the MPN-SAF TSS cytokine symptom cluster (TSS-C) (Vannucchi et al, 2015). The TSS-C is the sum of individual scores for tiredness, itching, muscle aches, night sweats and sweats while awake, each rated on a scale of 0 (absent) to 10 (worst imaginable). The requirement for TSS-C score ≥8 (i.e., mean score ≥1.6 on each of the 5 individual components) was implemented to ensure that patients had an adequate symptom score at baseline to assess meaningful changes in the primary endpoint. The TSS clusters were identified using an empirical statistical factor analysis of baseline MPN-SAF scores from the phase 3 RESPONSE trial (Vannucchi et al, 2015). This analysis divided the 14 individual MPN-SAF symptoms into 3 symptom clusters independent of presumed pathophysiological mechanisms. From a clinical perspective, the 3 symptom clusters agreed well with 3 presumptive pathophysiological mechanisms associated with PV-related symptoms (cytokines, hyperviscosity and splenomegaly). Eligible patients had ≤2 phlebotomies in the 6 months before screening or no palpable splenomegaly; therefore, the TSS-C was chosen to define patient eligibility and the primary endpoint. Eligible patients also had haematocrit values between 35% and 48% before randomization; had recovered from all phlebotomy-associated adverse events, with ≥1 week elapsed between the last phlebotomy and baseline; and had an Eastern Cooperative Oncology Group performance status of 0–2 at baseline. Patients with inadequate liver or renal function, platelet count <100 x 10^9/l, neutrophil count <1 x 10^9/l, or peripheral blood blast count >0% at screening were not eligible.

Study design

RELIEF (ClinicalTrials.gov identifier, NCT01632904) was a randomized, multicentre, double-blind, double-dummy, phase 3b clinical trial evaluating ruxolitinib versus HC in patients with PV reporting disease-related symptoms while receiving a stable dose of HC (Fig 1). Eligible patients were randomized 1:1 to receive ruxolitinib (10 mg twice daily)
plus HC placebo or HC (prerandomization dose and schedule) plus ruxolitinib placebo.

Treatment dose modifications were permitted for safety and efficacy and to optimize response for each patient. HC dose modifications were per investigator judgment; increases to a dose that was not previously tolerated were not permitted. Ruxolitinib dose increases were permitted for patients demonstrating both inadequate efficacy (defined as \( \geq 1 \) of the following: haematocrit \( \geq 45\% \) or >40\% and \( \geq 3 \) percentage points above baseline; white blood cell or platelet count above the upper limit of normal; reduction from baseline in palpable spleen length of <25\% at Week 4 and <50\% at Week 8; or minimal improvement, no change or worsening on the Patient Global Impression of Change (PGIC)) and adequate haematological parameters (defined as platelet count \( \geq 140 \times 10^9/l \), haemoglobin \( \geq 120 \text{ g/l} \), and absolute neutrophil count \( \geq 1.5 \times 10^9/l \)). Blood counts were assessed at Day 1 and every 4 weeks during the blinded treatment phase, and every 12 weeks starting at Week 24 during the open-label treatment phase. For patients who crossed over to ruxolitinib, blood counts were also assessed at 4 and 8 weeks after crossover. Ruxolitinib dose increase was also permitted after a prior dose reduction for safety. Ruxolitinib dose increases were permitted in the absence of select grade 1 cytopenias; dose reductions or interruptions were required for select grade \( \geq 2 \) cytopenias. Dose modifications were made to the study drug and placebo to ensure continued blinding, where applicable.

After the 16-week blinded treatment phase, patients in either treatment arm with adequate haematological parameters (i.e., platelet count \( \geq 100 \times 10^9/l \), neutrophil count \( \geq 1 \times 10^9/l \) and haemoglobin \( \geq 120 \text{ g/l} \)) were eligible to receive open-label ruxolitinib until study completion at Week 48.

**Endpoints**

The primary endpoint was the proportion of patients with \( \geq 50\% \) reduction (improvement) from baseline in TSS-C at Week 16. Secondary endpoints included the proportion of patients with \( \geq 50\% \) reduction (improvement) from baseline in individual TSS-C symptom severity scores at Week 16 and safety parameters, including nonhaematological and haematological adverse events. Exploratory endpoints included median changes from baseline in TSS-C individual symptom severity scores at Week 16 and the proportion of patients reporting treatment-related improvements in PV symptoms at Week 16 using the PGIC (Dworkin et al, 2005).

**Assessments**

Polycythaemia vera–related symptom severity was assessed with the MPN-SAF questionnaire once during screening between Days –28 and –7 (using a 7-day recall), daily during the baseline phase between Days –7 and –1, and daily starting at randomization and continuing until the end of treatment. Baseline score was defined as the average score during the 7 days before randomization (a minimum of 4 days of TSS-C scores was required before randomization). The Week 16 TSS-C score was defined as the average over the last 28 days before the Week 16 visit. Week 16 scores were considered missing if there were \( <20 \) days of data recorded before the Week 16 visit.

The single-item PGIC instrument asks patients to grade changes in their PV-related symptoms since starting study treatment using the following response options: “very much improved” to “much improved”, “minimally improved”, “no change”, “minimally worse”, “much worse” and “very much worse” (Dworkin et al, 2005). Patient responses on the PGIC were captured at Weeks 4, 8, 12, and 16.

**Safety**

All adverse events, regardless of causality, were assessed according to the National Cancer Institute. Common Terminology Criteria for Adverse Events, version 3.0 (2016 http://ctep.cancer.gov/protocolDevelopment/electronic_applications/docs/ctcaev3.pdf). Haematological adverse events were evaluated based on laboratory values.

**Statistical analyses**

A previous study of patients with primary myelofibrosis (MF), post-PV MF or post–essential thrombocythaemia-MF...
found that approximately 46% who received ruxolitinib and 5% who received placebo experienced a ≥50% reduction (improvement) in total symptom score at Week 24 (Verstovsek et al, 2012). As such, the sample size of the current study was selected based on an assumption that ≥35% of patients in the ruxolitinib arm and 7.5% of patients in the HC arm would achieve a ≥50% reduction (improvement) in TSS-C at Week 16. Based on this assumption, a sample size of 100 patients (n = 50 per treatment arm) would provide 90% power (2-sided alpha, 0.05).

Efficacy endpoints were evaluated in the intent-to-treat population, with the following exception: for analyses of individual TSS-C symptom scores, patients were excluded if scores were either missing at baseline or 0 at baseline and Week 16; patients with a score of 0 at baseline and a score >0 at Week 16 were considered nonresponders and included in the analyses. The safety analysis set included all randomized patients who received ≥1 dose of study treatment.

The primary endpoint was estimated with 95% confidence intervals (CIs); the odds ratio (OR) and corresponding 95% CIs were also calculated for the primary endpoint using the Fisher exact test.

A post hoc subgroup analysis was performed to evaluate the association between changes in TSS-C during the time between screening and baseline (up to 3 weeks) and corresponding changes in TSS-C at Week 16. The proportion of patients achieving ≥50% improvement in TSS-C at Week 16 was calculated among patient subgroups with TSS-C screening-to-baseline ratios ≤2 or >2; 95% CIs were calculated using the Clopper-Pearson exact method, and P values were calculated using the chi-square test.

A second post hoc analysis evaluated the effect of treatment dose modifications during the blinded treatment phase on changes in TSS-C. The proportion of patients achieving ≥50% improvement in TSS-C at Week 16 was calculated among those who required a dose reduction, maintained a consistent dose, and required a dose increase from baseline to Weeks 13 through 16. The coefficient of determination was used to evaluate the correlation between individual changes in study treatment dose from baseline to Weeks 13 through 16 and the percentage change in TSS-C.

Treatment adherence was assessed using pill counts recorded by study site staff members and calculated for each patient as the percentage of the intended dose (i.e., sum of doses prescribed by the investigator) that was taken.

All other analyses were summarized by descriptive statistics.

**Results**

**Patient characteristics and treatment adherence**

In total, 110 patients were randomized between 2 July 2012 and 27 March 2014 (ruxolitinib, n = 54; HC, n = 56; Fig 2). Median age at baseline was similar between the treatment arms (Table I), and most patients did not have baseline

---

Fig 2. Patient disposition. HC, hydroxycarbamide. *Arterial occlusive disease, blurred vision, diarrhea, fatigue, increased platelet count, muscular weakness, musculoskeletal and connective tissue disorders, pyrexia, unstable angina, upper abdominal pain, and urinary tract pain; ≥1 adverse event could be the cause of discontinuation in a given patient. †Deep vein thrombosis. ‡Data cut-off for this analysis occurred when the last patient completed the Week 16 visit. Patients were still in the blinded phase at data cut-off if the unblinding date was missing or occurred after the cut-off date.
white blood cell or platelet counts higher than European LeukaemiaNet thresholds (Barosi et al, 2013) (white blood cell count, 10 × 10⁹/l; platelet count, 400 × 10⁹/l). The majority of patients in the ruxolitinib arm were women, whereas the majority of patients in the HC arm were men. A greater proportion of patients in the ruxolitinib arm had a history of thromboembolic events (ruxolitinib, 33-3%; HC, 21-4%). The median treatment adherence rate was 98-3% in the ruxolitinib arm and 97-7% in the HC arm. A total of 35 patients randomized to the ruxolitinib arm and 36 patients randomized to the HC arm began open-label treatment with ruxolitinib after completing the double-blind phase (Fig 2).

**Efficacy**

The primary endpoint, ≥50% improvement from baseline in TSS-C at Week 16, was achieved by 43-4% of patients in the ruxolitinib arm and 29-6% in the HC arm; however, the difference between arms was not statistically significant (OR, 1-82; 95% CI, 0-82–4-04; P = 0-139; Table II). There was a trend towards a greater proportion of patients in the ruxolitinib arm achieving ≥50% improvement from baseline in the individual TSS-C symptoms compared with the HC arm; however, only the difference for itching was statistically significant (OR, 2-51; 95% CI, 1-10–5-71; P = 0-027; Table II). In addition, there was a trend towards greater improvement in the median percentage change from baseline in the individual TSS-C symptoms in favour of ruxolitinib at Week 16 (Table III). Treatment with ruxolitinib during the unblinded treatment phase (randomized ruxolitinib and crossover) was associated with continued benefit based on the median percentage change from baseline in TSS-C and individual TSS-C symptom severity scores at 24 and 48 weeks after initiation of ruxolitinib therapy (Table III). The proportion of patients who achieved a ≥50% improvement in the MPN-SAF TSS or splenomegaly-related symptoms was similar between the treatment arms (data not shown), as expected for this PV patient population with generally well-controlled haematocrit and/or no splenomegaly.

Some patients reported large changes in symptom severity between screening and baseline, with TSS-C symptom scores at least twice as severe at screening compared with baseline in 15/53 (28-3%) evaluable patients in the ruxolitinib arm and 10/54 (18-5%) evaluable patients in the HC arm. Therefore, a post hoc subgroup analysis was performed among patients with relatively stable TSS-C scores between screening and baseline (i.e, screening-to-baseline TSS-C ratio ≤2). Among these patients, a significantly greater proportion in the ruxolitinib arm compared with the HC arm achieved a ≥50% improvement from baseline in TSS-C at Week 16 (ruxolitinib, 47-4%; HC, 25-0%; P = 0-0346; Table IV). The proportion of patients who achieved a ≥50% reduction from baseline in TSS-C at Week 16 was not significantly different between treatment arms for patients with a screening-to-baseline TSS-C ratio >2.

HC, hydroxycarbamide; OR, odds ratio; MPN-SAF TSS-C, Myeloproliferative Neoplasm Symptom Assessment Form total symptom score cytokine symptom cluster.

*For individual symptoms within the TSS C cluster, all patients with a score >0 at baseline were included in the analysis. If the baseline score was 0 and Week 16 score was >0, the patient was considered a nonresponder. If the baseline and Week 16 scores were both 0, the patient was excluded from the responder analysis.

†The denominator is the number of evaluable patients.

Dose modifications occurred in 24 patients in the ruxolitinib arm (reduction, n = 11; increase, n = 13) and 21 patients in the HC arm (reduction, n = 9; increase, n = 12). There was no statistically significant correlation between changes in treatment dose from baseline to Weeks 13 through 16 and the percentage change in TSS-C in either treatment arm (coefficient of determination: ruxolitinib arm, 0.018; HC arm, 0.030). Among patients who continued to receive the same HC dose between baseline and Weeks 13–16, 34.3% achieved ≥50% improvement in TSS-C (Table V).

Using the PGIC, a greater proportion of patients in the ruxolitinib arm reported that their PV-related symptoms were "very much improved" or "much improved" at Week 16 as a result of treatment (ruxolitinib, 48.1%; HC, 30.4%; OR, 2.13; 95% CI, 0.98–4.65), whereas patients in the HC arm were more likely to describe their symptoms as "minimally improved" or "no change" (ruxolitinib, 33.3%; HC, 55.4%). The proportions of patients who reported each PGIC response option are presented in Fig 3.

Safety

Adverse events during blinded treatment are summarized in Table VI. Events were primarily grades 1 or 2 in both treatment arms. The most common nonhaematological adverse events in the ruxolitinib arm included fatigue, headache, and dizziness. Diarrhoea, constipation, fatigue, and pruritus were the most common nonhaematological adverse events in the HC arm. Anaemia and thrombocytopenia were mainly grades 1 or 2 in each treatment arm. Five patients in the ruxolitinib arm and 4 patients in the HC arm experienced serious adverse events during blinded treatment: thromboembolic events occurred in 2 patients in the ruxolitinib arm and 2 patients in the HC arm.

Herpes zoster infection was observed in 1 patient in the ruxolitinib arm during blinded treatment; no patients received prophylaxis treatment for herpes zoster infection before or during the trial. During blinded treatment, squamous cell carcinoma was observed in 1 patient in the ruxolitinib arm, and no patients had disease transformation to MF or acute myeloid leukaemia (AML). After completion of the blinded treatment phase, 1 additional patient in the ruxolitinib arm developed squamous cell carcinoma and 1 patient in the ruxolitinib arm was diagnosed with disease

HC, hydroxycarbamide; MPN-SAF TSS-C, Myeloproliferative Neoplasm Symptom Assessment Form total symptom score cytokine symptom cluster.

*All patients with a score >0 at baseline were included in the analysis.

†Treatment duration: (1) after baseline in the ruxolitinib and HC groups; (2) after crossover from HC to ruxolitinib in the ruxolitinib crossover group.
Four patients in the ruxolitinib arm and 1 patient in the HC arm discontinued because of adverse events (Fig 2). There were 2 deaths during the trial, both of which occurred after completion of the blinded treatment phase; 1 patient died from pneumonia after discontinuing HC but before crossing over to ruxolitinib, and 1 patient randomized to ruxolitinib died because of transformation to AML.

Discussion

This report of the RELIEF trial primary results indicates that for patients with generally well-controlled PV receiving a stable dose of HC, a change in treatment to ruxolitinib monotherapy was associated with a positive trend in symptom improvement compared with those continuing on HC, although this trend was not statistically significant. At Week 16, median changes from baseline in all individual TSS-C symptom scores favoured ruxolitinib and were still improving at Week 48. Itching was the symptom with the most pronounced improvements observed with ruxolitinib at Week 16. Patients who crossed over to ruxolitinib after randomization to HC experienced improvements in all individual TSS-C symptom scores within 8 weeks of ruxolitinib treatment; symptom scores stabilised or continued to improve with 48 weeks of treatment. However, data on long-term and crossover treatment with ruxolitinib were limited by small patient populations. Patient-reported improvements in symptom severity were better with ruxolitinib compared with HC; a greater proportion of patients receiving ruxolitinib reported that their symptoms were “very much improved” or “much improved”.

This randomized clinical trial is the first in patients with MPNs to evaluate symptoms as the primary endpoint and provides important insights into how best to design future trials in this setting with regard to statistical power and the impact of perceived eligibility criteria. An important limitation of this study was that it did not anticipate, and therefore underestimated, the relatively high proportion of patients who achieved the primary endpoint in the HC arm.

Fig 3. Patient Global Impression of Change at Week 16. *HC, hydroxycarbamide. Percentage of patients with missing data: ruxolitinib, 13-0%; HC, 7-1%. *N is the number of patients in each treatment arm; n is the number of patients who selected each response option.

This randomized clinical trial is the first in patients with MPNs to evaluate symptoms as the primary endpoint and provides important insights into how best to design future trials in this setting with regard to statistical power and the impact of perceived eligibility criteria. An important limitation of this study was that it did not anticipate, and therefore underestimated, the relatively high proportion of patients who achieved the primary endpoint in the HC arm.
including those who received a consistent HC dose from baseline to Weeks 13 to 16 (34%). The reason for this finding is unclear. Although compliance in a clinical trial may be better than in clinical practice, this is an unlikely explanation because previous findings in patients with PV suggest that HC treatment is not associated with clinically relevant improvements in symptoms (Johansson et al, 2012; Scherber et al, 2012; Mesa et al, 2015; Geyer et al, 2016). However, randomized controlled trial data addressing this question are lacking. It is also possible that patients in RELIEF experienced closer medical follow-up and better availability of supportive measures that may not be typical of standard care settings, which would suggest a potential for better patient outcomes with improved supportive care. Some patients may have entered the study with an expectation of symptomatic relief, which may have contributed to a placebo effect. The substantial difference between symptom scores at screening (reported using a 1-week recall) and baseline (average of daily reporting) suggests a possible over-reporting bias for some patients at screening, which may have been affected by patient awareness of the eligibility requirement for pronounced symptoms. In support of this concept, a post hoc subgroup analysis demonstrated that patients with relatively stable TSS-C between screening and baseline were significantly more likely to achieve ≥50% improvement in TSS-C at Week 16 with ruxolitinib versus HC. These data suggest that the lower than expected baseline scores for some patients may have compromised the ability to observe clinically relevant changes from baseline during study treatment. Gender differences in treatment response and symptom assessment may also have affected study results; a smaller proportion of patients in the ruxolitinib arm were male compared with the HC arm. Finally, the study was not designed or powered to evaluate measures other than symptoms, precluding evaluation of other clinical outcomes including changes in blood counts and spleen volume.

Previous phase 3 studies suggest that ruxolitinib improves symptoms compared with best available therapy (including HC) in patients with MF or PV. In patients with MF, there is evidence of meaningful improvement in symptoms with ruxolitinib versus placebo, as evaluated by the MPN-SAF (Mesa et al, 2013), and versus best available therapy (47% receiving HC) using the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire–Core 30 (EORTC QLQ-C30) (Harrison et al, 2012). Similar findings were observed in the randomized, open-label, multicentre, phase 3 RESPONSE trial, which evaluated ruxolitinib versus best available therapy (59% receiving HC) in patients with PV who were intolerant of or resistant to HC (Vannucchi et al, 2015). Exploratory analyses of changes in symptom severity from baseline to Week 32 demonstrated that ruxolitinib was associated with greater improvements in items on the MPN-SAF, EORTC QLQ-C30, and Pruritus Symptom Impact Scale (Vannucchi et al, 2015) compared with lesser improvements or worsening symptoms/quality of life with best available therapy. There were several important differences between the patient populations included in RESPONSE and RELIEF that may explain why the ruxolitinib symptom results were not in agreement between these studies. RESPONSE included a larger patient population

HC, hydroxy carbamide.

*Per the National Cancer Institute Common Terminology Criteria for Adverse Events, version 3-0.

†Adverse events reported by >10% of patients in either arm.

‡New or worsening haematology laboratory values; n indicates the number of patients with abnormal laboratory values, N indicates the number of evaluable patients (patients were evaluable for new or worsening grade 3/4 haematology laboratory values if post-baseline data were available and data were missing at baseline or the severity at baseline was grade ≤2).
(N = 222) with a more severe disease state compared with RELIEF (N = 110). In RESPONSE, patients were required to have splenomegaly at baseline and to be intolerant of or resistant to HC. In contrast, RELIEF patients were generally well controlled with HC but experienced persistent PV-related symptoms. At baseline, patients randomized to ruxolitinib in RESPONSE versus RELIEF had a longer median duration of PV (98.4 months vs. 58.5 months), longer median palpable spleen length (7.0 cm vs. 0.0 cm), higher mean blood counts (white blood cell, 17.6 × 10^9/l vs. 9.0 × 10^9/l; platelet, 484.5 × 10^9/l vs. 357.4 × 10^9/l), and a higher mean JAKV617F allele burden (76.2% vs. 29.0%) (Vannucchi et al, 2015).

The safety and tolerability profile of ruxolitinib observed in RELIEF was consistent with that reported in previous phase 2 and 3 studies of patients intolerant of or resistant to HC (Verstovsek et al, 2014; Vannucchi et al, 2015). Adverse events were generally grades 1 or 2, with few patients (7.4%) discontinuing ruxolitinib treatment because of an adverse event.

In conclusion, treatment with ruxolitinib was associated with a nonsignificant trend towards improvements in TSS-C compared with HC in patients who had generally well-controlled PV with a stable dose of HC but still reported disease-associated symptoms. A statistically significant improvement in itching was observed with ruxolitinib compared with HC, trends towards improvements with ruxolitinib were observed in all other symptoms, and patients with stable screening-to-baseline TSS-C were less likely to report responses to treatment with HC. The large proportion of patients achieving the primary endpoint while continuing to receive a stable HC dose was unexpected and may have implications for the design of future clinical trials.
