REGULARIZED COMPUTATION OF APPROXIMATE PSEUDOINVERSE OF LARGE MATRICES USING LOW-RANK TENSOR TRAIN DECOMPOSITIONS

NAMGIL LEE† AND ANDRZEJ CICHOCKI‡

Abstract. We propose a new method for low-rank approximation of Moore-Penrose pseudoinverses (MPPs) of large-scale matrices using tensor networks. The computed pseudoinverses can be useful for solving or preconditioning of large-scale overdetermined or underdetermined systems of linear equations. The computation is performed efficiently and stably based on the modified alternating least squares (MALS) scheme using low-rank tensor train (TT) decompositions and tensor network contractions. The formulated large-scale optimization problem is reduced to sequential smaller-scale problems for which any standard and stable algorithms can be applied. Regularization technique is incorporated in order to alleviate ill-posedness and obtain robust low-rank approximations. Numerical simulation results illustrate that the regularized pseudoinverses of a wide class of non-square or nonsymmetric matrices admit good approximate low-rank TT representations. Moreover, we demonstrated that the computational cost of the proposed method is only logarithmic in the matrix size given that the TT-ranks of a data matrix and its approximate pseudoinverse are bounded. It is illustrated that a strongly nonsymmetric convection-diffusion problem can be efficiently solved by using the preconditioners computed by the proposed method.

Key words. Alternating least squares (ALS), density matrix renormalization group (DMRG), curse of dimensionality, solving of huge system of linear equations, low-rank tensor approximation, matrix product operators, matrix product states, preconditioning, generalized inverse of huge matrices, tensor networks, big data.

1. Introduction. In this paper, we consider the approximate numerical solution of very large-scale systems of linear equations

\[ Ax = b, \quad A \in \mathbb{R}^{I \times J}, \quad b \in \mathbb{R}^I. \]

In the case that both the number of equations \( I \) and the number of unknowns \( J \) have an exponential rate of increase, e.g., \( I = P^N \) and \( J = Q^N \) with \( N \geq 20 \) and \( P, Q \geq 2 \), standard numerical solution methods cannot be applied directly without exploiting structure of the matrix such as the sparsity due to high computational and storage costs. Such an exponential increase with size of the matrix is referred to as the curse of dimensionality. For example, standard numerical methods for solving high-dimensional partial differential equations often become intractable as the dimensionality of the involved operators and functions increases. We consider structured matrices with billions of rows and columns and beyond, without any assumption that the data matrix is sufficiently sparse.

In order to break the curse of dimensionality, low-rank tensor decomposition techniques are gaining growing attention in numerical computing and signal processing [6, 9, 10, 23, 33, 52]. A tensor of order \( N \) is an \( N \)-dimensional array. Higher-order tensors arise from various sources such as multi-dimensional data analysis [11, 34]

and high-dimensional problems in scientific computing [23, 33]. Tensor decomposition techniques transform such higher-order tensors into low-parametric data representation formats. Comprehensive surveys about traditional tensor decomposition methods such as CANDECOMP/PARAFAC (CP) and Tucker formats are provided in [11, 34]. However, traditional tensor decomposition methods have limitations in high-order tensor approximation and numerical computing [23, 33]. On the other hand, modern tensor decomposition methods such as the hierarchical Tucker (HT) [22, 26] and tensor train (TT) formats [41, 44] are promising tools for breaking down the curse of dimensionality. For instance, once large-scale matrices and vectors are reshaped into higher-order tensors and represented approximately in TT format (e.g., see [30, 32]), basic algebraic operations such as addition and matrix-by-vector multiplication can be performed with logarithmic storage and computational complexity [41].

We mostly focus on the TT format, which is equivalent to the matrix product states (MPS) with open boundary conditions (OBC) in quantum physics [51]. Algorithms for solving optimization problems using TT formats, due to its simple linear structure of separation of variables (or dimensions), are often presented in simple recursive forms, please see, e.g., TT-rank truncation algorithm [41].

However, previous studies on numerical algorithms for solving systems of linear equations based on TT formats focus mostly on the cases of square data matrices, i.e., $A \in \mathbb{R}^{I \times J}$ with $I = J$; see, e.g., TT-GMRES [15], alternating least squares (ALS) [28], modified alternating least squares (MALS) [28], density matrix renormalization group (DMRG) [43], and alternating minimal energy (AMEn) [17]. In order to apply the existing algorithms to the case of non-square or strongly nonsymmetric coefficient matrices, the normal equation $A^T A x = A^T b$ can be considered, in which the solution is equivalent in the sense of minimum of the linear least squares problem. However, the matrix product $A^T A$ is often extremely ill-conditioned since the singular values of $A$ are squared. The ill-conditioning can slow down the convergence rate and reduce accuracy of developed algorithms.

Our main objective is to develop a new method to compute an approximation to the Moore-Penrose pseudoinverse (MPP) of $A$, i.e., $P^T \approx A^+ \in \mathbb{R}^{J \times I}$, and solve the preconditioned system

$$P^T A x = P^T b,$$

when $I \geq J$, or $A P^T y = b$ with the substitution $x = P^T y$ when $I \leq J$. The preconditioned matrix $P^T A$ (resp. $A P^T$) should be square and near symmetric, and have more uniformly distributed eigenvalues possibly far away from zero to improve the convergence property of an iterative method.

We can compute an approximate MPP $P^T \approx A^+ \in \mathbb{R}^{J \times I}$ by minimizing the cost function

$$F_\lambda(P) = \|I_J - P^T A\|_F^2 + \lambda\|P\|_F^2, \quad \lambda \geq 0,$$

assuming without loss of generality that $I \geq J$. The objective function (1.3) with $\lambda = 0$ has been considered widely for the computation of preconditioners by, e.g., sparse approximate inverse (SPAI) preconditioners [5, 24] and generalized approximate inverse (GAINV) preconditioners [12]. Most approximate inverse techniques are claimed to be largely immune to the risk of breakdown during the preconditioner construction [5]. The general case that $\lambda \geq 0$ was considered by, e.g., the optimal low-rank regularized inverse matrix approximation [7, 8]. The regularization term is
helpful for alleviating ill-posedness of the minimization problem (1.3) and improving the convergence property of the proposed algorithm. The simulation results in Section 4 illustrate that the regularization approach is also helpful for avoiding overestimation of TT-ranks of the pseudoinverses.

We propose a new method for computing the approximate generalized inverse $P^T$ in the form of a low-rank TT decomposition. Many of the sparse approximate inverse algorithms such as the SPAI preconditioners [24] assume that approximate inverses are sparse, however, inverses of sparse matrices are often not sparse. On the other hand, matrices represented in TT format do not have to be sparse, instead, they are required to have relatively small TT-ranks. It has been shown that inverses and preconditioners of several classes of important matrices such as Laplace-like operators and banded Toeplitz matrices admit approximate low-rank TT representations [4, 30, 31, 32, 45].

Holtz, Rohwedder, and Schneider [28] and Oseledets and Dolgov [43] developed DMRG (also called as MALs) methods for solving systems of linear equations with square matrices in TT formats. The application to matrix inversion is presented in [43]. However, the matrix inversion method proposed in [43] is applicable only to square matrices. And when we want to apply this approach, the linear matrix equation $P^T A = I$ is converted to a larger linear least squares (LS) problem. On the other hand, the proposed method can be applied to general non-square matrices, whose pseudoinverses can be efficiently computed without a need to solve a larger linear LS problem. Finally, once an approximate pseudoinverse is computed, the preconditioned linear system can be solved by applying existing TT-based optimization algorithms such as the ones developed in [17, 42, 43]. Numerical simulation results illustrate that the approximate generalized inverses obtained by the proposed method provide usually low TT-ranks with a sufficiently small approximation error. The resulting preconditioned linear systems can be solved by existing TT-based algorithms much faster than linear systems without preconditioning. A wide class of structured matrices in TT format are considered and demonstrated to have low TT-rank preconditioners.

The paper is organized as follows. In Section 2, we describe briefly mathematical representations for TT decomposition. In Section 3, we design a new tensor network and develop a MALs algorithm for computing approximate pseudoinverses. In Section 4, experimental results are presented to demonstrate the validity and effectiveness of the proposed method. In Section 5, discussion and concluding remarks are given.

2. The TT Decompositions.

2.1. Notation. We will briefly describe notation for tensors and tensor operations used in this paper. We refer to [11, 14, 34] for further details. Scalars, vectors, and matrices are denoted by lower-case letters (a, b, . . . ), lower-case bold letters (a, b, . . . ), and upper-case bold letters (A, B, . . . ), respectively. Nth-order tensors, i.e., N-way arrays (for $N \geq 3$), are denoted by calligraphic letters (A, B, . . . ). For a tensor $X \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$, where $I_n$ is the size of the nth mode, the $(i_1, i_2, \ldots, i_N)$th entry of $X$ is denoted by $x_{i_1, i_2, \ldots, i_N}$. Mode-n fibers of a tensor $X \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ are column vectors $x_{i_1, \ldots, i_{n-1}, i_{n+1}, \ldots, i_N} \in \mathbb{R}^{I_n}$ determined by fixing all the indices except for the nth index. The mode-1 contracted product of tensors $A \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ and $B \in \mathbb{R}^{J_1 \times J_2 \times \cdots \times J_M}$ is a binary operation defined by the tensor

\[ A \bullet B \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_{N-1} \times J_2 \times J_3 \times \cdots \times J_M} \]
with entries

$$(A \bullet B)_{i_1, i_2, \ldots, i_{N-1}, j_2, j_3, \ldots, j_M} = \sum_{i_N=1}^{I_N} a_{i_1, i_2, \ldots, i_N} b_{i_N, j_2, j_3, \ldots, j_M}. $$

The mode-1 contracted product is a natural generalization of the matrix-by-matrix product to higher-order tensors. Note that it has associativity: $(A \bullet B) \bullet C = A \bullet (B \bullet C)$ for any tensors $A, B,$ and $C$ of proper sizes.

Basic symbols for tensor are shown in Figure 1. In particular, symbols for vectors (1st-order tensors), matrices (2nd-order tensors), and 3rd-order tensors are illustrated in Figure 1(a), while the mode-1 contraction of two 3rd-order tensors is illustrated in Figure 1(b).

Indices $i_1, i_2, \ldots, i_N,$ which run through $i_n = 1, 2, \ldots, I_n,$ can be grouped in a single multi-index $i_1 i_2 \cdots i_N.$ The following two notations are defined based on the multi-index.

**Definition 2.1.** For a fixed $n \in \{1, 2, \ldots, N\}$, the $n$th canonical matricization of a tensor $X \in \mathbb{R}^{I_1 \times \cdots \times I_N}$ is defined by the matrix $[27]$

$$(2.2) \quad X_{(n)} \in \mathbb{R}^{I_1 i_2 \cdots i_n, i_{n+1} \cdots I_N},$$

with entries

$$(X_{(n)})_{i_1 i_2 \cdots i_n, i_{n+1} \cdots i_N} = x_{i_1, i_2, \ldots, i_N}. $$

**Definition 2.2.** For a fixed $n \in \{1, 2, \ldots, N\}$, the mode-$n$ matricization of a tensor $X \in \mathbb{R}^{I_1 \times \cdots \times I_N}$ is defined by the matrix $[34]$

$$(2.3) \quad X_{(n)} \in \mathbb{R}^{I_n \times i_1 i_2 \cdots i_{n-1} i_{n+1} \cdots I_N},$$

with entries

$$(X_{(n)})_{i_n, i_1 i_2 \cdots i_{n-1} i_{n+1} \cdots i_N} = x_{i_1, i_2, \cdots, i_N}. $$

The multi-index can be defined by either the big-endian $i_1 i_2 \cdots i_N = i_N + (i_{N-1} - 1) I_N + \cdots + (i_1 - 1) I_2 I_3 \cdots I_N$ or the little-endian $i_1 i_2 \cdots i_N = i_1 + (i_2 - 1) I_1 + \cdots + (i_{N-1} - 1) I_1 I_2 \cdots I_{N-1}$. In this paper, we use the little-endian convention unless otherwise mentioned.
Note that the columns of the mode-$n$ matricization $X_{(n)}$ are the mode-$n$ fibers of $\mathcal{X}$. Moreover, the vectorization of a tensor $\mathcal{X} \in \mathbb{R}^{I_1 \times \cdots \times I_N}$ is defined as the $N$th canonical matricization

\[(2.4) \quad \text{vec}(\mathcal{X}) \equiv \mathbf{x}_{(N)} \in \mathbb{R}^{I_1 I_2 \cdots I_N},\]

whose entries are $(\text{vec}(\mathcal{X}))_{i_1 i_2 \cdots i_N} = x_{i_1, i_2, \ldots, i_N}$.

### 2.2. The HT Format.

The hierarchical Tucker (HT) and tensor train (TT) formats are low-parametric representations for vectors, matrices, and higher-order tensors. The HT format, introduced by Hackbusch and his coworkers [25, 26], can be considered as a more general model than the TT format, but most techniques for TT format can be extended to HT format and the generalization is often straightforward, e.g., see [36].

Let $V = V^{(1)} \otimes \cdots \otimes V^{(N)}$ be a tensor product space, where $V^{(n)}$ $(1 \leq n \leq N)$ are Hilbert spaces. For example, we can consider that $V^{(n)} = \mathbb{R}^{I_n}$ with the inner product defined by $\langle \mathbf{v}, \mathbf{w} \rangle = \mathbf{v}^T \mathbf{w}$, or $V^{(n)} = \mathbb{R}^{I_n \times J_n}$ with $\langle V, W \rangle = \text{trace}(V^T W)$. For $N > 1$, a binary tree $T_N$ is called a dimension tree if

(a) all nodes $t \in T_N$ are non-empty subsets of $\{1, \ldots, N\}$,

(b) the set $t_{\text{root}} = \{1, \ldots, N\}$ is the root node of $T_N$, and

(c) each node $t \in T_N$ with $|t| \geq 2$ has two children $t_1, t_2 \in T_D$ such that $t$ is a disjoint union $t = t_1 \cup t_2$.

A dimension tree determines recursive partitioning of the modes $\{1, \ldots, N\}$, e.g., see Figures 2(a) and (b). We denote the set of all leaf nodes by $L \subset T_N$ and the set of children of a non-leaf node $t$ by $S(t) \subset T_N$.

Let $(R_t)_{t \in T_N}$ be positive integers with $R_{t_{\text{root}}} = 1$. An element $\mathbf{x} \in V$ is an HT tensor with $T_N$-rank bounded by $(R_t)_{t \in T_N}$ if

(a) there exists a finite dimensional subspace $U^{(t)} = \text{span}\{u^{(t)}_{r_t} : 1 \leq r_t \leq R_t\} \subset V^{(t)}$ for each leaf node $t \in L$, and

(b) there exists a coefficient tensor $G^{(t)} \in \mathbb{R}^{R_{t_1} \times R_{t_2} \times R_t}$ for each non-leaf node $t \in T_N \setminus L$, such that

(c) intermediate vectors $u^{(t)}_{r_t} \in \bigotimes_{n=1}^N V^{(n)}$ $(1 \leq r_t \leq R_t)$ for each non-leaf node $t \in T_N \setminus L$ are defined recursively by

\[(2.5) \quad u^{(t)}_{r_t} = \sum_{r_{t_1}}^{R_{t_1}} \sum_{r_{t_2}}^{R_{t_2}} g^{(t)}_{r_{t_1}, r_{t_2}} u^{(t_1)}_{r_{t_1}} \otimes u^{(t_2)}_{r_{t_2}}, \quad \{t_1, t_2\} = S(t),\]

and $\mathbf{x}$ is represented by $\mathbf{x} = u^{(t_{\text{root}})}_{r_{t_{\text{root}}}}$.

For example, if the tree $T_N$ is the binary tree as illustrated in Figure 2(a), then a corresponding HT tensor $\mathbf{x} \in V$ can be written as

\[
\mathbf{x} = u^{(1,2,3,4)}_{1} = \sum \cdots \sum g^{(1,2,3,4)}_{1,2,3,4} g^{(1,2)}_{1,2} g^{(3,4)}_{3,4} \ u^{(1)}_{1} \otimes u^{(2)}_{2} \otimes u^{(3)}_{3} \otimes u^{(4)}_{4}.
\]

This rather abstract representation in (2.5) can be immediately applied to the cases when $V^{(n)} = \mathbb{R}^{I_n}$ or $V^{(n)} = \mathbb{R}^{I_n \times J_n}$.

### 2.3. The TT Format.

The TT format, introduced in scientific computing by Oseledets and his coworkers [41, 42, 43, 44, 45], can be considered as a special case of the HT format when the dimension tree has a linear structure, such as the example
The TT representations for large scale vectors, matrices, and higher-order tensors can also be derived from the recursive definition of the HT format in (2.5).

If we suppose that \( V^{(n)} = \mathbb{R}^{I_n} \), then a large scale vector \( x \in \mathbb{R}^{I_1 \times \cdots \times I_N} \equiv V \) can be represented in TT format by sums of Kronecker products

\[
(2.6) \quad x = \sum_{r_1=1}^{R_1} \sum_{r_2=1}^{R_2} \cdots \sum_{r_{N-1}=1}^{R_{N-1}} x_{1;\cdots;I_1}^{(1)} \otimes x_{r_1;\cdots;I_2}^{(2)} \otimes \cdots \otimes x_{r_{N-1};\cdots;1}^{(N)},
\]

where \( x_{I_1;\cdots;I_n}^{(n)} \in \mathbb{R}^{I_n} \) are mode-2 fibers of 3rd-order tensors \( \mathcal{X}^{(n)} \in \mathbb{R}^{R_{n-1} \times I_n \times R_n} \). The 3rd-order tensors \( \mathcal{X}^{(n)} \) are called TT-cores, \( R_1, R_2, \ldots, R_{N-1} \) are called TT-ranks, and we define \( R_0 = R_N = 1 \). We assume for convenience that the first and the last TT-cores (matrices) are also 3rd-order tensors of size \( 1 \times I_1 \times R_1 \) and \( R_{N-1} \times I_N \times 1 \), respectively. We call the TT representations in (2.6) (for large-scale vectors) as the vector TT format, which is equivalent to the MPS with open boundary conditions (OBC) (see Figure 3(a)(top)).

A higher-order tensor \( \mathcal{X} \in \mathbb{R}^{I_1 \times \cdots \times I_N} \) is said to be represented in TT format if its vectorization \( \text{vec}(\mathcal{X}) \in \mathbb{R}^{I_1 \times \cdots \times I_N} \) is represented in TT format (2.6), i.e., \( x = \text{vec}(\mathcal{X}) \). In this case, the tensor \( \mathcal{X} \) can be expressed by the mode-1 contracted products of 3rd-order TT-cores (see Figure 3(a)(top))

\[
(2.7) \quad \mathcal{X} = \mathcal{X}^{(1)} \bullet \mathcal{X}^{(2)} \cdots \bullet \mathcal{X}^{(N)},
\]

where \( \mathcal{X}^{(n)} \in \mathbb{R}^{R_{n-1} \times I_n \times R_n} \) are the 3rd-order TT-cores.

Note that TT decompositions (2.7) of a tensor \( \mathcal{X} \) may not be unique, and the TT-ranks \( R_1, \ldots, R_{N-1} \) depend on a specific decomposition. From (2.7), we have \( \text{rank}(\mathcal{X}^{(n)}_{(n)}) \leq R_n, \ n = 1, \ldots, N-1 \). However, if a TT decomposition of a tensor \( \mathcal{X} \) is minimal, i.e., all TT-cores have full left and right rank as \( \text{rank}(\mathcal{X}^{(n)}_{(n)}) = R_n \) and \( \text{rank}(\mathcal{X}^{(n)}_{(i)}) = R_{n-1} \), then the TT-ranks of minimal TT decompositions are unique and satisfy \( \text{rank}(\mathcal{X}^{(n)}_{(n)}) = R_n, \ n = 1, \ldots, N-1 \). The TT-ranks of a tensor \( \mathcal{X} \) is defined as the TT-ranks of a minimal TT decomposition. See [25, 27] for more details.

The storage cost can be significantly reduced if large-scale vectors and matrices can be approximately represented in TT formats with relatively small TT-ranks. For example, the storage complexity for a vector \( x \in \mathbb{R}^{I_1 \times \cdots \times I_N} \) represented in TT format is \( O(NQR^2) \) with \( Q = \max_n(I_n) \) and \( R = \max_n(R_n) \) [41].

On the other hand, if we suppose that \( V^{(n)} = \mathbb{R}^{J_n \times J_n} \), then a large scale matrix \( A \in \mathbb{R}^{I_1 \times \cdots \times I_N \times J_1 \cdots J_N} \equiv V \) can be represented in TT format as sums of Kronecker...
products

\[
\mathbf{A} = \sum_{r_1^A=1}^{R_1^A} \cdots \sum_{r_{N-1}^A=1}^{R_{N-1}^A} \mathbf{A}_{1}^{(1)} \otimes \mathbf{A}_{1,\cdots:r_2^A}^{(2)} \otimes \cdots \otimes \mathbf{A}_{r_{N-1}^A;\cdots:1}^{(N)},
\]

where \(\mathbf{A}_{r_{n-1}^A;\cdots;1}^{(n)} \in \mathbb{R}^{I_n \times J_{n-1} \times R_{n-1}^A}\) are the slice matrices of 4th-order core tensors \(\mathbf{A}^{(n)} \in \mathbb{R}^{R_{n-1}^A \times I_n \times J_{n-1} \times R_n^A}\), and \(R_1^A, R_2^A, \ldots, R_{N-1}^A\) are TT-ranks with \(R_0^A = R_N^A = 1\). The TT format for large-scale matrices in (2.8) is equivalent to the matrix product operators (MPO) in quantum physics [51], and we refer to it as the matrix TT format (see Figure 3(b)(top)).

### 2.4. Extraction of Core Tensor for Matrix TT Format.

For practical and theoretical purposes, we will introduce alternative representations for large-scale matrices based on the matrix TT format or MPO, which will be used for describing the proposed algorithm.

The vectorization, which is an operation on matrices, can be extended to matrices represented in matrix TT format as follows. Let \(I = I_1 I_2 \cdots I_N\) and \(J = J_1 J_2 \cdots J_N\). For a matrix \(\mathbf{A} \in \mathbb{R}^{I \times J}\) in matrix TT format (2.8) with TT-cores \(\mathbf{A}^{(n)} \in \mathbb{R}^{R_{n-1}^A \times I_n \times J_{n-1} \times R_n^A}\), the extended vectorization of \(\mathbf{A}\) can be defined by the vector in TT format, with slight abuse of our notation,

\[
\text{vec}(\mathbf{A}) = \sum_{r_1^A=1}^{R_1^A} \cdots \sum_{r_{N-1}^A=1}^{R_{N-1}^A} \text{vec}(\mathbf{A}_{1;\cdots;r_2^A}^{(1)}) \otimes \cdots \otimes \text{vec}(\mathbf{A}_{r_{N-1}^A;\cdots;1}^{(N)}) \in \mathbb{R}^{IJ},
\]

i.e., each of the 4th-order TT-cores \(\mathbf{A}^{(n)}\) is reshaped into the 3rd-order TT-core of size \(R_{n-1} \times I_n J_n \times R_n\).

Let

\[
\mathbf{p} = \text{vec}(\mathbf{P}) \in \mathbb{R}^{IJ}
\]
denote the extended vectorization (2.9) of a large-scale matrix \( P \in \mathbb{R}^{I \times J} \) in matrix TT format whose 4th-order TT-cores can be reshaped into 3rd-order cores

\[
\mathcal{P}(n) \in \mathbb{R}^{K_{n-1} \times K_n \times R_n}, \quad K_n = I_n J_n, \quad \forall n,
\]

for the corresponding vector \( p \). From the expression (2.7), the \( N \)-th order tensor \( P \in \mathbb{R}^{K_1 \times \cdots \times K_N} \) determined by \( p = \text{vec}(P) \) can be written as the mode-1 contracted products (see Figure 4)

\[
P = \mathcal{P}^{(1)} \cdot \mathcal{P}^{(2)} \cdots \cdot \mathcal{P}^{(N)} \in \mathbb{R}^{K_1 \times K_2 \times \cdots \times K_N}.
\]

For \( n = 1, 2, \ldots, N \), the mode-1 contracted products of left TT-cores and right TT-cores are respectively denoted by

\[
\mathcal{P}^{<n} = \mathcal{P}^{(1)} \cdot \mathcal{P}^{(2)} \cdots \cdot \mathcal{P}^{(n-1)} \in \mathbb{R}^{K_1 \times \cdots \times K_{n-1} \times R_{n-1}},
\]

\[
\mathcal{P}^{>n} = \mathcal{P}^{(n+1)} \cdot \mathcal{P}^{(n+2)} \cdots \cdot \mathcal{P}^{(N)} \in \mathbb{R}^{R_n \times K_{n+1} \times \cdots \times K_N},
\]

and we define \( \mathcal{P}^{<1} = \mathcal{P}^{>N} = 1 \). The \( N \)-th order tensor \( P \in \mathbb{R}^{K_1 \times \cdots \times K_N} \) can be rewritten by

\[
P = \mathcal{P}^{<n} \cdot \mathcal{P}^{(n,n+1)} \cdot \mathcal{P}^{>n+1}, \quad n = 1, 2, \ldots, N - 1,
\]

where

\[
\mathcal{P}^{(n,n+1)} = \mathcal{P}^{(n)} \cdot \mathcal{P}^{(n+1)} \in \mathbb{R}^{R_{n-1} \times K_n \times K_{n+1} \times R_{n+1}}
\]

is the mode-1 contracted product of the two neighboring TT-cores. The so-called frame matrix [28, 35] for our model is defined by

\[
P^f = \left( \mathcal{P}^{(n+1)} \right)^T \otimes I_{K_{n+1}} \otimes I_{K_n} \otimes \left( \mathcal{P}^{<n} \right)^T \in \mathbb{R}^{IJ \times R_{n-1} K_n K_{n+1} R_{n+1}},
\]

where \( \mathcal{P}^{<n} \in \mathbb{R}^{R_{n-1} \times K_1 \cdots K_{n-1}} \) and \( \mathcal{P}^{(n+1)} \in \mathbb{R}^{R_{n+1} \times K_{n+2} \cdots K_N} \) are the mode-\( n \) and mode-1 matricizations of the tensors \( \mathcal{P}^{<n} \) and \( \mathcal{P}^{>n+1} \), respectively.

From the expressions (2.12) and (2.13), we can derive an expression for the vector \( p = \text{vec}(P) \) (2.10) as a product of the frame matrix and a local vector \( p_n \):

\[
p = P^f p_n \in \mathbb{R}^{IJ}, \quad n = 1, 2, \ldots, N - 1,
\]

where

\[
p_n = \text{vec}(\mathcal{P}^{(n,n+1)} \in \mathbb{R}^{R_{n-1} K_n K_{n+1} R_{n+1}}
\]
is the vectorization of the merged TT-core $\mathcal{P}^{(n,n+1)}$.

In order to simplify computation and improve efficiency of our algorithm, we need to orthogonalize core tensors. For this purpose, left- or right-orthogonalization of the 3rd-order TT-cores $\mathcal{P}^{(n)} \in \mathbb{R}^{R_{n-1} \times K_n \times R_n}$ is defined as follows [27].

**Definition 2.3 (Left- or right-orthogonalization [27]).** A 3rd-order tensor $\mathcal{U} \in \mathbb{R}^{I \times J \times K}$ is called left-orthogonalized if its mode-1 matricization $\mathcal{U}(1) \in \mathbb{R}^{K \times IJ}$ has orthonormal rows as

$$
\mathcal{U}(3)\mathcal{U}^T(3) = I_K,
$$

and right-orthogonalized if its mode-1 matricization $\mathcal{U}(1) \in \mathbb{R}^{I \times JK}$ has orthonormal rows as

$$
\mathcal{U}^T(1)\mathcal{U}(1) = I_J.
$$

We note that the left- or right-orthogonalization of 4th-order TT-cores $\mathcal{P}^{(n)} \in \mathbb{R}^{R_{n-1} \times I_n \times J_n \times R_n}$ can be defined by the left- or right-orthogonalization of the reshaped 3rd-order TT-cores $\mathcal{P}^{(n)} \in \mathbb{R}^{R_{n-1} \times K_n \times R_n}$, where $K_n = I_nJ_n$. The left- or right-orthogonalized 4th-order tensors $\mathcal{P}^{(n)} \in \mathbb{R}^{R_{n-1} \times I_n \times J_n \times R_n}$ are denoted by the tensor network diagram shown in Figure 1(c). We can show that the mode-$n$ matricization $\mathcal{P}^{(n)}$ and the mode-1 matricization $\mathcal{P}^{(n+1)}$ have orthonormal rows if the TT-cores $\mathcal{P}^{(1)}, \ldots, \mathcal{P}^{(n-1)}$ are left-orthogonalized and $\mathcal{P}^{(n+2)}, \ldots, \mathcal{P}^{(N)}$ are right-orthogonalized [38]. Consequently, the frame matrix $\mathcal{P}^F$ in (2.13) will have orthonormal columns if the TT-cores are properly left- or right-orthogonalized.

3. Computation of Approximate Pseudoinverse Using TT Decomposition. Without loss of generality, we assume that $I \geq J$ for a large-scale matrix $\mathbf{A} \in \mathbb{R}^{I \times J}$ with $I = I_1I_2\cdots I_N$ and $J = J_1J_2\cdots J_N$. We formulate the following optimization problem: for $\lambda \geq 0$,

$$
\begin{aligned}
\min_{\mathcal{P}} & \quad \|\mathcal{I}_J - \mathcal{P}^T\mathcal{A}\|_F^2 + \lambda\|\mathcal{P}\|_F^2 \\
\text{s.t.} & \quad \mathcal{P} \in \mathcal{T}_{\leq \overline{R}} \subset \mathbb{R}^{I \times J},
\end{aligned}
$$

(3.1)

where $\mathcal{T}_{\leq \overline{R}}$ denotes the set of TT tensors of TT-ranks bounded by rank $\overline{R} = (R_{1}, \ldots, R_{N-1})$. We denote the cost function by $F_\lambda(\mathcal{P}) = \|\mathcal{I}_J - \mathcal{P}^T\mathcal{A}\|_F^2 + \lambda\|\mathcal{P}\|_F^2$. We assume that the matrix $\mathbf{A} \in \mathbb{R}^{I \times J}$ is given in matrix TT format (2.8).

3.1. Modified Alternating Least Squares (MALS) Algorithm. In the MALS scheme, for each $n \in \{1, 2, \ldots, N-1\}$ at each iteration, only the $n$ and $(n+1)$th TT-cores are optimized while the other TT-cores are fixed. The large-scale optimization problem (3.1) can then be reduced to a set of much smaller scale optimization problems as we explain below.

Note that the cost function in (3.1) can be expressed, in matrix form, as

$$
F_\lambda(\mathcal{P}) = J + \text{trace} \left( \mathcal{P}^T\mathbf{A}\mathbf{A}^T\mathcal{P} - 2\mathcal{P}^T\mathcal{A} + \lambda\mathcal{P}^T\mathcal{P} \right).
$$

Let $\mathbf{p} = \text{vec}(\mathbf{P}) \in \mathbb{R}^{IJ}$ denote the extended vectorization (2.9) of the matrix $\mathbf{P} \in \mathbb{R}^{I \times J}$. From the matrix TT representation (2.8), we can derive that

$$
\text{vec}(\mathbf{A}^T\mathbf{P}) = (\mathcal{I}_J \otimes \mathbf{A}^T)\mathbf{p} = (\mathcal{I}_J \otimes \mathbf{A})^T\mathbf{p},
$$

(3.2)
where $I_f \otimes A \in \mathbb{R}^{I_f \times J_f}$ denote the (extended) Kronecker product defined by Kronecker products between core tensors as

$$I_f \otimes A = \sum_{r_f^{A_1}=1}^{R_f^{A_1}} \cdots \sum_{r_f^{A_{N-1}}=1}^{R_f^{A_{N-1}}} (I_{J_f} \otimes A_{1,\ldots,r_f^{A_1}}^{(1)}) \otimes \cdots \otimes (I_{J_f} \otimes A_{1,\ldots,r_f^{A_{N-1}};\ldots;1}^{(N)}).$$

Using the expressions (3.2), we can express $F_\lambda(P)$ in the vectorized form as

$$F_\lambda(p) = J + p^T (I_f \otimes AA^T)p - 2p^T a + \lambda p^T p,$$

where $a = \text{vec}(A) \in \mathbb{R}^{IJ}$. From the expression (2.14) and the orthogonality of the columns of the frame matrix $P^\perp$, $F_\lambda(P)$ can be further simplified as

$$(3.3) \quad F_\lambda(p_n) = J + p_n^T \overline{A}_n p_n - 2p_n^T \overline{B}_n + \lambda p_n^T p_n,$$

where $\overline{A}_n$ and $\overline{B}_n$ are the relatively small-scale matrices and vectors defined by

$$(3.4) \quad \overline{A}_n = (P^\perp)^T (I_f \otimes AA^T)P^\perp \in \mathbb{R}^{R_{n-1}K_nK_{n+1}R_{n+1} \times R_{n-1}K_nK_{n+1}R_{n+1}}$$

and

$$(3.5) \quad \overline{B}_n = (P^\perp)^T \text{vec}(A) \in \mathbb{R}^{R_{n-1}K_nK_{n+1}R_{n+1}}, \quad n = 1, \ldots, N-1.$$

Finally, we can obtain a set of reduced linked optimization problems:

$$\min_{p_n} \quad p_n^T \overline{A}_n p_n - 2p_n^T \overline{B}_n + \lambda p_n^T p_n$$

s.t. $p_n = \text{vec}(P^{(n,n+1)}) \in \mathbb{R}^{R_{n-1}K_nK_{n+1}R_{n+1}},$

for $n = 1, 2, \ldots, N-1$. It should be noted that the size of the matrix $\overline{A}_n$ can be much smaller than $AA^T$ under the condition that $R_{n-1}$ and $R_{n+1}$ are relatively low and bounded.

Figure 5 illustrates a tensor network diagram representing the cost function $\text{trace}(P^T AA^T P - 2P^T A^{(n,n+1)}P^{(n,n+1)})$ both in matrix and vectorized forms. The trace is indicated by the blue line connecting the start block with the end block (e.g., see Figure 1(d)). In order to solve the optimization problem (3.1), each matrix is represented approximately in matrix TT format. The large-scale optimization problem can then be reduced to a smaller-scale optimization problem, where the reduced cost functions are described as $p_n^T \overline{A}_n p_n - 2p_n^T \overline{B}_n + \lambda p_n^T p_n$ $(n = 1, 2, \ldots, N-1)$.

The relatively small-scale matrix $\overline{A}_n$ and vector $\overline{B}_n$ in the reduced local problem can be computed efficiently by recursive contractions of the core tensors in the tensor network diagram in Figure 5. The recursive computation procedure for the tensor network contractions can be described as follows. Let $Z_1^{(m)} \in \mathbb{R}^{(R_{m-1} R_{m+1})^2 \times (R_m R_m^{A})^2}$ and $Z_2^{(m)} \in \mathbb{R}^{R_{m-1} R_{m+1} \times R_m R_m^{A}}$ be matrices defined by

$$Z_1^{(m)} = \sum_{i_m,j_m,j'_m} F^{(m)}_{i_m,j_m,j'_m} \otimes A^{(m)}_{i_m,j_m,j'_m} \otimes A^{(m)}_{i_m,j'_m,j'_m} \otimes F^{(m)}_{i_m,j'_m,j'_m},$$

$$Z_2^{(m)} = \sum_{i_m,j_m} F^{(m)}_{i_m,j_m,j_m} \otimes A^{(m)}_{i_m,j_m,j_m}, \quad m = 1, \ldots, N,$$
TT-cores of problems, which are expressed by minimization of cost functions:

\[ \text{The large-scale optimization problem is reduced to set of equivalent and much smaller optimization}\]

\[ \text{optimization of the } n \]

\[ \text{vec } \]

\[ \text{Fig. 5 Conceptual tensor network diagrams for the trace}(P^T A A^T P - 2 \lambda P^T P) \text{ for the}
\]

\[ \text{optimization of the } n \]

\[ \text{Optimization problem is reduced to set of equivalent and much smaller optimization}\]

\[ \text{problems, which are expressed by minimization of cost functions:} \]

\[ \text{such that } p_n = \text{vec}(P^{n,n+1}) \in \mathbb{R}^{k_n k_{n+1} r_{n+1}} (1 \leq n \leq N - 1). \text{ The left- and right-orthogonalized TT-cores of } P \text{ are indicated by the half-filled squares.} \]
where \( \overline{\mathbf{P}}^{(m)} \in \mathbb{R}^{R_{m-1} \times I_m \times J_m \times R_m} \) and \( \mathcal{A}^{(m)} \in \mathbb{R}^{R_{m-1} \times I_m \times J_m \times R_m} \) are the 4th-order TT-cores for the matrices \( \mathbf{P}, \mathcal{A} \in \mathbb{R}^{I \times J} \) in matrix TT format (2.8). Note that the trace terms in the cost function \( F_\lambda(\mathbf{P}) \) can be expressed by

\[
\text{trace}(\mathbf{P}^T \mathcal{A} \mathcal{A}^T \mathbf{P}) = \mathbf{Z}_1^{(1)} \mathbf{Z}_2^{(2)} \cdots \mathbf{Z}_1^{(N)}, \quad \text{trace}(\mathbf{P}^T \mathcal{A}) = \mathbf{Z}_2^{(1)} \mathbf{Z}_2^{(2)} \cdots \mathbf{Z}_2^{(N)}.
\]

Two 4th-order tensors \( \mathcal{L}_1^{<m} \) and \( \mathcal{R}_1^{>m} \) and two matrices \( \mathbf{L}_2^{<m} \) and \( \mathbf{R}_2^{>m} \) with sizes

\[
\mathcal{L}_1^{<m} \in \mathbb{R}^{R_{m-1} \times R_{m-1}^A \times R_m \times R_m}, \quad \mathcal{R}_1^{>m} \in \mathbb{R}^{R_m \times R_m^A \times R_m \times R_m},
\]

\[
\mathbf{L}_2^{<m} \in \mathbb{R}^{R_{m-1} \times R_m^A \times R_m \times R_m}, \quad \mathbf{R}_2^{>m} \in \mathbb{R}^{R_m \times R_m^A \times R_m \times R_m},
\]

are defined recursively by, for \( p = 1, 2 \),

\[
(3.7) \quad \text{vec}(\mathcal{L}_p^{<m}) = 1, \quad \text{vec}(\mathcal{L}_p^{<m})^T = \text{vec}(\mathcal{L}_p^{<m-1})^T \mathbf{Z}_p^{(m-1)}, \quad m = 2, 3, \ldots, n,
\]

\[
(3.8) \quad \text{vec}(\mathcal{R}_p^{>N}) = 1, \quad \text{vec}(\mathcal{R}_p^{>m}) = \mathbf{Z}_p^{(m+1)} \text{vec}(\mathcal{R}_p^{>m+1}), \quad m = N - 1, N - 2, \ldots, n + 1.
\]

The tensor \( \mathcal{L}_1^{<m} \) defined in (3.7) can be efficiently computed by contractions of the tensors \( \{\mathcal{L}_1^{<m-1}, \mathcal{P}^{(m-1)}, \mathcal{A}^{(m-1)}, \mathcal{A}^{(m-1)}, \mathcal{P}^{(m-1)}\} \). The tensor \( \mathcal{R}_1^{>m} \) and matrices \( \mathbf{L}_2^{<m} \) and \( \mathbf{R}_2^{>m} \) can be computed similarly.

Finally, the matrix \( \overline{\mathbf{A}}_n \) can be computed by contractions of the tensors \( \{\mathcal{L}_1^{<m}, \mathcal{A}^{(n)}, \mathcal{A}^{(n)}, \mathcal{A}^{(n+1)}, \mathcal{A}^{(n+1)}, \mathcal{R}_1^{>n+1}\} \), as illustrated in Figure 5. The vector \( \overline{\mathbf{b}}_n \) can be computed by contractions of the tensors \( \{\overline{\mathbf{A}}_2^{<n}, \mathcal{A}^{(n)}, \mathcal{A}^{(n+1)}, \mathcal{A}_2^{(n+1)}\} \). In practice, however, the local matrix \( \mathbf{A}_n \) is not computed explicitly, but the matrix-by-vector multiplication \( \overline{\mathbf{A}}_n \mathbf{x} \) for some \( \mathbf{x} \in \mathbb{R}^{R_{n-1} K_n K_{n+1} R_{n+1}} \) is used by standard iterative methods. See Section 3.2.8 for more detail.

After the solution, the resulting merged tensor \( \mathcal{P}^{(n,n+1)} = \mathcal{P}^{(n)} \circ \mathcal{P}^{(n+1)} \) is decomposed into two separate TT-cores via the \( \delta \)-truncated SVD [41]: for the matrix \( \mathbf{P}^{(n,n+1)} \in \mathbb{R}^{R_{n-1} K_n K_{n+1} R_{n+1}} \),

\[
(3.9) \quad [\mathbf{U}_1, \mathbf{S}_1, \mathbf{V}_1] = \text{SVD}_\delta \left( \mathbf{P}^{(n,n+1)} \right),
\]

with the subsequent updates \( R_n = \min(\text{rank}(\mathbf{U}_1), \overline{\mathbf{A}}_n), \mathbf{P}^{(n)} = \mathbf{U}_1, \text{ and } \mathbf{P}^{(n+1)} = \mathbf{S}_1 \mathbf{V}_1^T \). In this way, the TT-ranks can be adaptively determined during the iteration process, and the TT-cores can be left- or right-orthogonalized.

The proposed MALS algorithm\(^3\) for the computation of an approximate Moore-Penrose pseudoinverse of large-scale matrices is described in Algorithm 1.

### 3.2. Properties and Practical Considerations.

#### 3.2.1. Existence and Uniqueness of Solution.

The proposed algorithm can be applied to general singular or non-singular structured matrices \( \mathbf{A} \in \mathbb{R}^{I \times J} \) provided in TT format. Moreover, it can be in quite straightforward way extended to the minimization of a more general objective function\(^4\)

\[
(3.10) \quad F_\lambda(\mathbf{P}; \mathbf{B}) = \|\mathbf{B}^T - \mathbf{P}^T \mathbf{A}\|_F^2 + \lambda \|\mathbf{P}\|_F^2,
\]

\(^3\)We have also developed an alternating least squares (ALS) algorithm (without merging two TT-cores), but its performance was slightly lower than the MALS algorithm presented here.

\(^4\)Representing regularized LS solution for \( \mathbf{AX} = \mathbf{B} \), where \( \mathbf{A} = \mathbf{A}^T \).
Algorithm 1: MALS algorithm for computing approximate pseudoinverse

**input**: $A \in \mathbb{R}^{I_1 \times J_{N-1} \times J_1 \times J_2 \times \cdots \times J_N}$ in matrix TT format, $\epsilon > 0$ (tolerance parameter), $\delta > 0$ (truncation parameter).

**output**: $P \in \mathbb{R}^{I_1 \times J_2 \times \cdots \times J_N \times I_{N-1} \times J_1}$ in matrix TT format with TT-cores $P^{(n)}$ ($1 \leq n \leq N$) and TT-ranks $R_1, R_2, \ldots, R_{N-1}$.

1. Initialize $P$ randomly with right-orthogonalized TT-cores $P^{(3)}, P^{(4)}, \ldots, P^{(N)}$.
2. Set $L_p^1 = 1, p = 1, 2$. Compute $R_p^n = \min(rank(U_1), R_n)$.
3. repeat
   for $n = 1, 2, \ldots, N-2$ do
     // Optimization
     Optimize $P^{(n,n+1)}$ by solving the local optimization problem (3.6).
     // Matrix Factorization by SVD
     Compute $\delta$-truncated SVD: $[U_1, S_1, V_1] = \text{SVD}_\delta(P^{(n,n+1)}_{\{2\}})$.
     Update $R_n = \min(rank(U_1), R_n)$.
     Update $P^{(n)} = \text{reshape}(U_1, R_{n-1} \times I_n \times J_n \times R_n)$.
     Update $P^{(n+1)} = \text{reshape}(S_1 V_1^T, R_n \times I_{n+1} \times J_{n+1} \times R_{n+1})$.
     Update $L_p^{n+1} = 1, p = 1, 2$ by (3.7).
   end
   for $n = N-1, N-2, \ldots, 2$ do
     Perform optimization and matrix factorization similarly
   end
4. until a stopping criterion is met (See (3.18));

where $B \in \mathbb{R}^{J \times L}$ is a given matrix in TT format and $P \in \mathbb{R}^{I \times L}$. For the above cost function, we can construct a similar tensor network as shown in Figure 5. A minimizer of the objective function $F_{\lambda}(P; B)$, without constraints, is known as a least squares (LS) solution. In the case that $\lambda > 0$, the solution is unique and it can be expressed by

$$
 P_{\lambda}^* = \left( A A^T + \lambda I \right)^{-1} A B, \quad \lambda > 0.
$$

On the other hand, if $\lambda = 0$, then the solution may not be unique and it can be expressed by

$$
 P_0^* = (A^\dagger)^T B + Z,
$$

where $Z \in \mathbb{R}^{J \times L}$ is any matrix satisfying $Z^T A = 0$. If $Z = 0$, then we call it a minimum-norm LS solution, and it is unique. If $B = I_J$, then the unique solution is equal to the (transposed) Moore-Penrose pseudoinverse. Furthermore, it has been shown that (see [2])

$$
 P_\lambda^* \to (A^\dagger)^T B \quad \text{as} \quad \lambda \to 0.
$$

The solution to the local optimization problem (3.6), which is also a standard LS problem, can be written in the same way by

$$
 P_0^* = \left( \overline{A}_n + \lambda I_{R_{n-1} \times R_{n-1} \times \cdots \times R_{n+1}} \right)^\dagger \overline{B}_n.
$$
Note that the local optimal solution (3.13) is the minimum-norm LS solution for the local optimization problem. Note that, from the expression (2.14), taking into account that the frame matrix $P^{\neq}$ has orthonormal columns,
\[
\|p_n\|_F^2 = \|P\|_F^2.
\]

3.2.2. Stability and Stopping Criterion. From (3.3), we note that the value of the objective function $F_\lambda(P)$ for the global optimization problem (3.1) is exactly the same as the value of the objective function for the local optimization problem (3.6) neglecting irrelevant constant $J$. Therefore, we can conclude that the value of the original objective function will monotonically decrease during the iteration process.

Proposition 3.1 (Monotonicity). Let $P_{\lambda,t} \in \mathbb{R}^{I \times J}$ denote the estimated solution at the iteration $t = 0, 1, 2, \ldots$, and $P_{\lambda,t+1}^* \in \mathbb{R}^{I \times J}$ the estimated solution obtained by replacing the $n$ and $(n+1)$th TT-cores of $P_{\lambda,t}$ with the solution $p_n^* = \text{vec}(P^{(n,n+1)*})$ to the reduced optimization problem (3.6). Then,
\[
F_\lambda(P_{\lambda,t}) \geq F_\lambda(P_{\lambda,t+1}^*).
\]

Moreover, we can easily compute the value of the global objective function from the value of the local objective function at each iteration. We define
\[
r_\lambda(P) = \frac{(F_\lambda(P))^{1/2}}{J^{1/2}},
\]
and call it as the relative residual. Note that the minimum value of $F_\lambda(P)$ can be expressed in terms of the singular values of the matrix $A$ as follows:
\[
F_\lambda^\min \equiv \min_{P \in \mathbb{R}^{I \times J}} F_\lambda(P) = F_\lambda(P_\lambda^*) = J - \sum_{r=1}^{\text{rank}(A)} \frac{\sigma_r^2}{\sigma_r^2 + \lambda},
\]
where $\sigma_r$ are the nonzero singular values of $A$. So, the minimum value of the relative residual is bounded as
\[
1 - \frac{\text{rank}(A)}{J} \leq \min_{P \in \mathbb{R}^{I \times J}} r_\lambda^2(P) = \frac{F_\lambda^\min}{J} \leq 1,
\]
where the lower bound can be attained when $\lambda = 0$, and the upper bound when $\lambda = \infty$.

Given a tolerance parameter $\epsilon > 0$, the stopping criterion of the MALS algorithm can be executed when a rate of decrease of the relative residual is smaller than $\epsilon$ as
\[
r_\lambda^2(P_{\lambda,t-N+2}) - r_\lambda^2(P_{\lambda,t}) < \epsilon^2 \cdot r_\lambda^2(P_{\lambda,t-N+2}).
\]
However, due to the machine precision, the computed $r_\lambda$ value can be not sufficiently precise if its value decreases to a very small value relative to the norm $\|I_j\|_F = J^{1/2}$. In this case, it should be computed directly using the matrices $A$ and $P$ represented in TT format, rather than indirectly using $A_n$, $b_n$, $P^{(n)}$, and $P^{(n+1)}$.

3.2.3. Selection of Truncation Parameter. The truncation parameter $\delta$ in the $\delta$-truncated SVD step affects the accuracy and the convergence speed. If $\delta$ is too small, estimated TT-ranks may increase fast and the computational cost can become
high. If $\delta$ is too large, on the other hand, the algorithm may not be able to achieve desired accuracy. Hence, a $\delta$ value determines the trade-off between computational cost and accuracy. We note that Oseledets [41] considered $\delta_0 = (N - 1)^{-1/2} \epsilon$ in the context of low-rank approximation, and Lee and Cichocki [39] set $\delta = 100\delta_0$ for the first $N - 1$ iterations and then set $\delta = \delta_0$ for the rest of the iterations. In our numerical simulations in this paper, we used a fixed value $\delta = 10^{-6}(N - 1)^{-1/2}$ unless mentioned otherwise.

3.2.4. Conditioning of Local Optimization Problems. Note that the contracted matrix $\overline{A}_n$ in the expression (3.4) is symmetric and positive definite, and the frame matrix $P^\square$ has orthonormal columns if the TT-cores $P^{(m)}$ $(m = 1, \ldots, n - 1)$ are left-orthogonalized and $P^{(m)} (m = n + 2, \ldots, N)$ are right-orthogonalized. Assuming the orthonormality of $P^\square$, we can show that (see [28])

$$\lambda_{\min}(AA^T) \leq \lambda_{\min}(\overline{A}_n) \leq \lambda_{\max}(\overline{A}_n) \leq \lambda_{\max}(AA^T),$$

where $\lambda_{\min}(M)$ and $\lambda_{\max}(M)$ are the minimum and maximum of the eigenvalues of a real symmetric matrix $M$, respectively. Therefore, keeping the TT-cores either left- and right-orthogonalized is important for running the MALS algorithm efficiently, especially when we use any standard iterative method for solving local optimization problems.

3.2.5. Avoiding Breakdowns. Some of the popular and efficient algorithms for computing preconditioners suffer from unexpected failures (which is often referred to as breakdowns) during the preconditioner construction step, e.g., in incomplete factorization methods [5]. On the other hand, the proposed MALS algorithm is free of such risks, because we can freely choose any efficient and reliable method for local factorization methods [5].

3.2.6. An Effect of Regularization to Convergence. The regularization term not only alleviates the ill-posedness of the optimization problem (3.1) (or more generally (3.10)), but also improves the convergence property of the proposed algorithm.

Let $P^*_\lambda$ be the global solution defined by (3.11), $P_{\lambda,t}$ the estimate at the current iteration $(t = 0, 1, 2, \ldots)$, and $R_{\lambda,t} = AB - (AA^T + \lambda I_I)P_{\lambda,t}$ the residual. Since $AB = (AA^T + \lambda I_I)P^*_\lambda$ for $\lambda > 0$, we can derive that (see also [3])

$$\|P^*_\lambda - P_{\lambda,t}\|_F^2 \leq \|AA^T + \lambda I_I\|^{-1}_2 \|R_{\lambda,t}\|_F^2 \leq \kappa_2(\lambda) \cdot \|P^*_\lambda\|_F^2 \cdot \|R_{\lambda,t}\|_F^2 \|AB\|_F^2$$

where $\kappa_2(\lambda) = \|AA^T + \lambda I_I\|_2 \|(AA^T + \lambda I_I)^{-1}\|_2$ is the spectral condition number of the matrix $AA^T + \lambda I_I$. It is clear that the larger the $\lambda$ value is, the smaller the values of $\kappa_2(\lambda)$ and $\|P^*_\lambda\|_F^2$ become. So, the regularization with $\lambda > 0$ reduces multiplicative factors on the right-hand side of (3.19), which improves the convergence speed of the current estimate $P_{\lambda,t}$ to the global solution $P^*_\lambda$.

3.2.7. Preconditioning of Large-Scale Systems of Linear Equations. The estimated pseudoinverse can be helpful for preconditioning of system of linear equations (see, (1.2).) By using the estimated preconditioner, we can convert overdetermined or underdetermined systems of linear equations into well-posed determined
systems. In addition, any nonsymmetric data matrix $A$ can be converted to a square
symmetric matrix approximately, as stated in the following proposition.

**Proposition 3.2 (Symmetricity).** Let $A \in \mathbb{R}^{I \times J}$ denote a given matrix with
$I \geq J$, $P^*_\lambda \in \mathbb{R}^{I \times J}$ the minimizer of $F_\lambda(P)$ defined in (3.11) and (3.12) with $B = I_J$, $F^\text{min}_\lambda$ the minimum value defined in (3.16), and

$$G_\lambda(P) = F_\lambda(P) - F^\text{min}_\lambda.$$ (3.20)

Then, it holds that, for any $\lambda \geq 0$ and $P \in \mathbb{R}^{I \times J}$,

$$\|P^T A - A^T P\|^2_F \leq 2G_\lambda(P) - 2\|P - P^*_\lambda\|^2_F. $$ (3.21)

For the proof of Proposition 3.2, we formulate the following lemma, which can be
derived immediately after some algebraic manipulation.

**Lemma 3.3.** For $\lambda \geq 0$,

$$G_\lambda(P) = F_\lambda(P) - F_\lambda(P^*_\lambda) = \|P^T A - P^*_\lambda^T A\|^2_F + \lambda\|P - P^*_\lambda\|^2_F. $$ (3.22)

**Proof.** Proof of Proposition 3.2. From Lemma 3.3, it follows that

$$\|P^T A - A^T P\|^2_F = \|P^T A - P^*_\lambda^T A + P^*_\lambda^T A - A^T P\|^2_F \leq 2\|P^T A - P^*_\lambda^T A\|^2_F$$

$$= 2G_\lambda(P) - 2\|P - P^*_\lambda\|^2_F.$$ 

The distribution of the eigenvalues and the singular values of the pre-conditioned
matrix $P^T A$ affects the convergence of an iterative method. The following theorem
states that the eigenvalues and the singular values of $P^T A$ obtained by the proposed
method can be made close to the eigen/singular values of the matrix $P^*_\lambda^T A$ by
decreasing the $G_\lambda(P)$ value.

**Theorem 3.3.** Let $A, P^*_\lambda \in \mathbb{R}^{I \times J}$ ($I \geq J$) and $G_\lambda(P)$ be defined as in Proposition 3.2. Then, for any $\lambda \geq 0$ and $P \in \mathbb{R}^{I \times J}$,

$$\sum_{r=1}^{J} |\lambda_r(P^T A) - \lambda_r(P^*_\lambda^T A)|^2 \leq G_\lambda(P) - \lambda\|P - P^*_\lambda\|^2_F, $$ (3.23)

$$\sum_{r=1}^{J} |\sigma_r(P^T A) - \sigma_r(P^*_\lambda^T A)|^2 \leq G_\lambda(P) - \lambda\|P - P^*_\lambda\|^2_F, $$ (3.24)

where $[N]_S = (N + N^T)/2$, $\lambda_r(M)$ are the eigenvalues of a real symmetric matrix $M$,$\sigma_r(N)$ are the singular values of a matrix $N$, and both $\lambda_r(M)$ and $\sigma_r(N)$ are arranged in decreasing order.

**Proof.** Since for any $M \in \mathbb{R}^{J \times J}$, it holds that $\|M\|^2_F - \|[M]_S\|^2_F = \|M - M^T\|^2_F/4 \geq 0$, we can derive, by the substitution $M = P^T A - P^*_\lambda^T A$, that

$$\|P^T A - P^*_\lambda^T A\|_F^2 \geq \|[P^T A]_S - P^*_\lambda^T A\|_F^2.$$ 

We can expand the right hand side of the above inequality as

$$\|P^T A|_S - P^*_\lambda^T A\|_F^2 = \|[P^T A]_S\|_F^2 + \|P^*_\lambda^T A\|_F^2 - 2 \cdot \text{trace} ([P^T A]_S \cdot A^T P^*_\lambda). $$ (3.25)
Note that, for a matrix $M \in \mathbb{R}^{J \times J}$ with a Shur decomposition $M = QTQ^T$, we have

$$\|M\|_F^2 = \|T\|_F^2 \geq \|\text{diag}(T)\|_2^2 = \sum_{r=1}^{J} |\lambda_r(M)|^2.$$ 

As it is stated in [37, Lemma II.1], the following relations hold: for any $J \times J$ Hermitian matrices $M$ and $N$,

$$\sum_{r=1}^{J} \lambda_r(M)\lambda_{J-r+1}(N) \leq \text{trace}(MN) \leq \sum_{r=1}^{J} \lambda_r(M)\lambda_r(N).$$

By using the above inequalities, we can derive that

$$\| [P^T A]_S - P^*_{\lambda} A \|_F^2 \geq \sum_{r=1}^{J} (|\lambda_r([P^T A]_S)|^2 + |\lambda_r(P^*_{\lambda} A)|^2 - 2\lambda_r([P^T A]_S)\lambda_r(P^*_{\lambda} A))$$

$$= \sum_{r=1}^{J} |\lambda_r([P^T A]_S) - \lambda_r(P^*_{\lambda} A)|^2.$$ 

The result in (3.23) follows using Lemma 3.3.

To prove the result in (3.24), we use the expression

$$\|P^T A - P^*_{\lambda} A\|_F^2 = \|P^T A\|_F^2 + \|P^*_{\lambda} A\|_F^2 - 2 \cdot \text{trace}(P^T A \cdot A^T P^*_{\lambda}).$$

For a matrix $M \in \mathbb{R}^{J \times J}$, we have $\|M\|_F^2 = \sum_{r=1}^{J} |\sigma_r(M)|^2$. By applying the von Neumann’s trace inequality [40], which states that, for $J \times J$ matrices $M$ and $N$,

$$|\text{trace}(MN)| \leq \sum_{r=1}^{J} \sigma_r(M)\sigma_r(N),$$

we can finally derive that

$$\|P^T A - P^*_{\lambda} A\|_F^2 \geq \sum_{r=1}^{J} |\sigma_r(P^T A) - \sigma_r(P^*_{\lambda} A)|^2.$$ 

Similarly, we can obtain the result in (3.24) by using Lemma 3.3.

From (3.23) of Theorem 3.4, we can say that the eigenvalues of the matrix $[P^T A]_S$ can become close to those of the symmetric positive semidefinite matrix $P^*_{\lambda} A$ when $G_{\lambda}(A)$ is small enough. If $A$ is of full column rank, then the smallest eigenvalue of $[P^T A]_S$ can approach $\lambda_J(P^*_{\lambda} A) = \sigma_J^2/(\sigma_J^2 + \lambda) > 0$, where $\sigma_J = \sigma_J(A)$, so the preconditioned matrix $P^T A$ can also become positive definite. In addition, from (3.24) of Theorem 3.4, the spectral condition number of $P^T A$ also can be made close to that of $P^*_{\lambda} A$ by decreasing $G_{\lambda}(P)$ gradually.

3.2.8. Computational Complexity. The most time-consuming step in the MALS algorithm is the optimization step for solving the reduced optimization problems (3.6). Let $Q = \max_n(I_n, J_n)$, $R = \max_n(R_n)$, and $R_A = \max_n(R_A^n)$. For a fast computation of the solution, we can apply standard iterative methods such as the gmres in Matlab for solving the system of linear equations $(\bar{X}_n + \lambda I_{R_n-1 \times K_{n+1} K_{n+1} R_{n+1}}) \bar{X}$.
by the iterative contraction of the tensors \( \{L_1^{<n}, A(n), A(n+1), A^{(n+1)}, R_1^{>n+1}\} \), as illustrated in Figure 6. The computational complexity for the multiplication \( \overline{A}_n x \) is \( O(R_3 R_2 Q^4 + R^2 R_3^3 Q^5) \). Since the computational cost for each iteration is independent of the order \( N \) if \( R, R_\alpha, \) and \( Q \) are bounded, the total computational cost for optimizing every TT-cores is logarithmic in the matrix size \( Q^N \times Q^N \).

On the other hand, the explicit computation of the matrix \( \overline{A}_n \) can be performed by the iterative contraction of the tensors \( \{L_1^{<n}, A(n), A(n+1), A^{(n+1)}, R_1^{>n+1}\} \), and its computational complexity is \( O(R_3 R_2 Q^4 + R^2 R_3^3 Q^5) \). Moreover, a direct method, such as the LU factorization or the pseudoinverse, for solving the system \( \overline{A}_n x = \overline{b}_n \) can cost up to \( O(R^n Q^n) \). The estimated preconditioner is reusable and does not need to be updated during the process of solving the preconditioned system of linear equations. However, the preconditioner \( P \) in the TT format needs to take small TT-ranks because the product \( P^T A \) increases the TT-ranks [41]. Note that in the case of sparse approximate inverse preconditioning techniques [5], similarly, the product \( P^T A \) would deteriorate sparsity of \( A \) even if both \( P \) and \( A \) are sparse. In such cases, the preconditioning can be performed implicitly.

4. Numerical Simulations. In the simulation study, we considered several matrices including rectangular matrices and nonsymmetric matrices in order to check validity and evaluate performance of the proposed MALS algorithm. We also compared the proposed method with an alternative method which applies a “standard” MALS method to solve the large scale system of linear equations (see also [43])

\[
(I_J \otimes AA^T + \lambda I_I \otimes I_J)\text{vec}(P) = \text{vec}(A).
\]

In practice, the matrix \( I_J \otimes AA^T \) is represented in matrix TT format with 4th-order TT-cores of the sizes \((R_{n-1}^\lambda)^2 \times I_n J_n \times I_n J_n \times (R_n^\lambda)^2\), \( n = 1, 2, \ldots, N \). Due to the relatively large sizes of the TT-cores, the computational cost for the matrix-by-vector multiplication in the standard MALS algorithm has complexity of \( O(R_3 R_2^3 Q^4 + R^2 R_3^3 Q^5) \) [43].

The TT-ranks of the estimated pseudoinverse were bounded by \( R = (50, \ldots, 50) \). We repeated the simulations 30 times with random initializations and averaged the results. In the simulation results, we calculated the value of the relative residual \( r_A \) (3.15) as described in Section 3.2.2. Our code was implemented in Matlab. We used the Matlab version of TT-Toolbox [42] for building and manipulating TT formats for large-scale matrices and vectors. Simulations were performed on a desktop computer.
with an Intel Core i7 4960X CPU at 3.60 GHz with 32 GB of memory running Windows 7 Professional and Matlab R2010b.

4.1. Example 1: Rectangular Circulant Matrices with Prescribed Singular Values. Rectangular matrices $A \in \mathbb{R}^{2^{N+1} \times 2^N}$ were defined by $A = \frac{1}{\sqrt{2}} C C^T$, where $C = [c_{i-j}]_{ij} \in \mathbb{R}^{2^N \times 2^N}$ are circulant matrices, i.e., $c_k = c_{k-2^N}, k = 0, 1, \ldots, 2^N - 1$, whose entries were determined in the following way. The (unordered) eigen/singular values of $C$ were first prescribed by, with $J = 2^N$, (see, Figure 7(a))

$$\sigma_j = f(j) = \frac{1}{B} \max \left( 0, \left| \frac{j}{J} - 0.5 \right| + B - 0.5 \right), \quad B > 0, \ j = 0, \ldots, J - 1.$$ 

Then, the entries $c_k$ of the circulant matrix $C$ were determined by the discrete Fourier inverse transform (IFFT) of the eigen/singular values [13], i.e., (see, Figure 7(b))

$$c_k = \text{ifft}(\sigma_j) = \frac{1}{J} \sum_{j=0}^{J-1} \sigma_j \exp \left( \frac{2\pi i j k}{J} \right).$$

The very large scale vector $[c_k]_k$ represented in TT format can be efficiently computed by the QTT-FFT algorithm [16], which is available in TT-Toolbox [42]. By construction, the matrix $A$ has the same singular values as $C$. We note that $A$ is ill-conditioned when $B \leq 0.5$.

Figure 8 illustrates that the relative residual decreases monotonically as the iteration proceeds. From Figure 8(a), we can see that the proposed algorithm converges relatively fast within one or two full sweeps (1 full sweep is equal to $2(N - 2)$ iterations) in the case that $\lambda > 0$, and the TT-ranks of the estimated pseudoinverse also remain at low values. On the other hand, without regularization (i.e., $\lambda = 0$), we can see that the convergence is slow, and the TT-ranks also grow very quickly during the iteration process.

For comparison of the computational costs, we set the tolerance parameter at $\epsilon = 0.2$. Figure 9 illustrates the computational costs and the estimated TT-ranks by the proposed MALS algorithm (MALS-PINV) and the standard MALS algorithm.
Fig. 8. Convergence of the proposed MALS algorithm for various values of the regularization parameter $\lambda$ for the $2^{N+1} \times 2^N$ rectangular circulant matrices with prescribed singular values and $N = 50, B = 0.5$. (a) Relative residual versus iteration, and (b) maximum of the TT-ranks of the estimated pseudoinverse versus iteration. The markers on the lines indicate half-sweeps, i.e., every $N - 2$ iterations.

(Std MALS), for various values of $20 \leq N \leq 100$ and $B \in \{0.3, 0.5, 0.7\}$. Some values of the computational time are not displayed in the figure if it was larger than 360 seconds. We can see that the computational costs increased only logarithmically with the matrix size $2^{N+1} \times 2^N$. The computation time of the proposed MALS algorithm was much smaller than that of the standard MALS algorithm (typically, by one or even two orders) as analyzed theoretically in Section 3.2.8 and in the first paragraph of Section 4. Moreover, the computation time for the regularized optimization with $\lambda > 0$ was shorter than that for the optimization without regularization, i.e., $\lambda = 0$. In addition, for the case of ill-conditioned matrices with either $B = 0.3$ or $B = 0.5$, no regularization with $\lambda = 0$ resulted in large estimated TT-ranks and high computational costs, whereas the regularization with $\lambda > 0$ significantly reduced estimated TT-ranks and also computational costs.

4.2. Example 2: Randomly Generated Matrices with Prescribed Singular Values. Nonsymmetric matrices $A \in \mathbb{R}^{2^N \times 2^N}$ were constructed in $N$-dimensional matrix TT format using

$$A = U\Sigma V^T,$$

where $\Sigma = \text{diag}(\sigma_0, \sigma_1, \ldots, \sigma_{2^N-1})$ is a diagonal matrix of singular values, and $U$ and $V$ are $2^N \times 2^N$ orthogonal matrices with TT-ranks equal to 1, i.e.,

$$U = U^{(1)} \otimes \cdots \otimes U^{(N)}, \quad V = V^{(1)} \otimes \cdots \otimes V^{(N)},$$

and $U^{(n)} \in \mathbb{R}^{2 \times 2}$ and $V^{(n)} \in \mathbb{R}^{2 \times 2}$ are randomly generated orthogonal matrices. The singular values were determined by

$$\sigma_j = 10^{-\frac{j}{2K_0}}, \quad j = 0, 1, \ldots, 2^N - 1,$$

for fixed $0 < K_0 \leq 1$. The largest singular value is equal to 1, and the singular values decay to zero as the index $j$ increases in a rate determined by $K_0$. The TT-ranks of the matrix $A$ and the inverse $A^{-1}$ are the same as those of $\Sigma$ and $\Sigma^{-1}$, respectively, which are $R_n^A = R_n^{A^{-1}} = 1$ ($1 \leq n \leq N - 1$).
Figure 9 illustrates the convergence of the proposed MALS algorithm for various values of the regularization parameter $\lambda$ for the matrices with $N = 50$ ($2^{50} \times 2^{50} \sim 10^{15} \times 10^{15}$) and $K_0 = 0.5$. The convergence was monotonic, i.e., the relative residual was nonincreasing during the iteration process. The larger $\lambda$ values resulted in larger relative residual values, as described in Section 3.2.2. Since the matrix $A$ is not ill-conditioned when $K_0 = 0.5$, the convergence was relatively fast, and the estimated TT-ranks were small. In Figure 10(b), when $\lambda = 0$ the estimated TT-ranks were $R_n = 1$, which are equal to the true TT-ranks of the inverse $A^{-1}$.

Figure 11(a) shows that the obtained minimal relative residual values were not different for various values of $N$, but they were different over various values of $K_0$. In addition, Figure 11(b) shows that the relative residual values were different for various values of the regularization parameter $\lambda$. The simulation results illustrated in Figures 11(a) and (b) are consistent and in agreement with the analysis in Section 3.2.2.

4.3. Example 3: Laplace Operator. The 1-D discrete Laplace operator of size $2^N \times 2^N$ with Dirichlet-Dirichlet boundary condition is considered [30]:

$$A = \text{tridiag}(-1, 2, -1) \in \mathbb{R}^{2^N \times 2^N}.$$  

The matrix $A$ is square and symmetric, and its explicit TT representation and TT-ranks were already investigated and presented in [30]. The TT-ranks of the inverse $A^{-1}$ are also known to be $(R_1, R_2, \ldots, R_{N-1}) = (4, 5, 5, \ldots, 5, 4)$ [30].

Figure 12 illustrates the convergence of the MALS algorithm for various values of $\lambda \in \{0, 10^{-6}, 10^{-4}, 10^{-2}\}$ and a fixed $N = 60$. The relative residual decreased monotonically, but the convergence was slow when the $\lambda$ value was small in the range $\lambda \in \{0, 10^{-6}\}$. In Figure 12(b), for the small $\lambda$ values, the maximum of the estimated
TT-ranks increased largely during the iteration process, whereas for the larger $\lambda$ values ($\lambda = 10^{-4}, 10^{-2}$), the TT-ranks were relatively small. Note that the values $\lambda = 10^{-4}, 10^{-2}$ are still relatively small compared to the diagonal entries of $AA^T$ in (3.11), which are 5 or 6. We can conclude that the regularization with a $\lambda > 0$ value is necessary to obtain low-rank approximate pseudoinverses of ill-conditioned large-scale matrices.

The computational costs for the estimation of the pseudoinverses are illustrated in Figure 13 together with the estimated maximum TT-ranks. It is illustrated that the computational time increased logarithmically with the matrix size $2^N \times 2^N$, and the estimated TT-ranks were bounded over all $N$ values. Moreover, the proposed MALS algorithm needs shorter computational time than the standard MALS algorithm.

4.4. Example 4: Convection-Diffusion Equation. In order to demonstrate the effectiveness of the proposed algorithm in preconditioning nonsymmetric systems...
of linear equations, we consider the 3-D convection-diffusion equation on the unit cube $[0, 1]^3$ described in [49]:

$$u_{xx} + u_{yy} + u_{zz} + cu_x = f,$$

where the function $f$ is defined by the solution

$$u(x, y, z) = \exp(xyz) \sin(\pi x) \sin(\pi y) \sin(\pi z).$$

By finite difference discretization, each axis is discretized by $2^M + 2$ grid points including the boundary points. The number of equations is $2^M \cdot 2^M \cdot 2^M = 2^{3M} = 2^N$ with $N = 3M$. We set $c = 2^{N-10}$. It is noted in [49] that the matrix $A$ is a strongly nonsymmetric matrix, and it has eigenvalues with large imaginary parts, which slow the convergence of conjugate gradient-type algorithms such as Bi-CGSTAB.

First, the regularized inverses of the coefficient matrix were estimated by the proposed algorithm. Figure 14 illustrates the convergence of the proposed algorithm.
Fig. 14. Convergence of the proposed MALS algorithm for various values of the truncation parameter $\delta = 2 \cdot 10^{-3}, 2 \cdot 10^{-5}, 2 \cdot 10^{-7}$ for the discretized convection-diffusion equation with $N = 30$ and $\lambda = 10^{-4}$. (a) Relative residual and (b) maximum of the TT-rank of the estimated pseudoinverse. The markers on the lines indicate half-sweeps, i.e., every $N - 2$ iterations.

Fig. 15. (a) Computation time, (b) maximum of the estimated TT-ranks, and (c) relative residuals obtained by the proposed MALS algorithm for the $2^N \times 2^N$ coefficient matrix of the convection-diffusion equation for various values of the regularization parameter $\lambda = 10^{-6}, 10^{-4}, 10^{-2}$.

for three truncation parameter values: $\delta = 2 \cdot 10^{-3}, 2 \cdot 10^{-5},$ and $2 \cdot 10^{-7}$. We can see that smaller $\delta$ values result in a faster convergence per each iteration, but the TT-ranks also increase faster, which may cause high computational costs. On the other hand, too large a value of $\delta$ may result in large relative residuals. Since the TT-ranks of the estimated pseudoinverse influence the computational cost in the next step of solving a preconditioned system of linear equations, it is important to balance the approximation accuracy and TT-ranks of the estimated pseudoinverse.

Figure 15 illustrates the computation time for the estimation of the regularized pseudoinverses, for various values of $N$ and regularization parameter $\lambda$, when the truncation parameter was set at $\delta = 10^{-4}(N - 1)^{-1/2}$. A large $\lambda$ value, e.g., $\lambda = 0.01$, resulted in relatively small TT-ranks and short computation time for $N = 15, 90$.

Next, we computed solutions to the convection-diffusion equation (4.2) numerically by using the function `dmrg_solve2` [43] in TT-Toolbox [42], where the linear equation was either preconditioned or not by the estimated regularized pseudoinverse. For solving local optimization problems in the `dmrg_solve2`, we used one of the three different Matlab functions, `gmres`, `bicgstab`, and `pcg`, in order to compare them for solving nonsymmetric systems of linear equations. However, we found almost no differences in performances between them in this simulation, so, we only presented the results of the `bicgstab`. The `dmrg_solve2` algorithm converged to the relative
residual tolerance of $10^{-4}$ within 20 full-sweeps mostly (one full-sweep is equivalent to solving the local problems $2(N - 2)$ times) for $15 \leq N \leq 90$. The computational costs for solving the linear systems are illustrated in Figures 16(a) and (b), where the preconditioned systems were solved much faster than without preconditioning. The estimated TT-ranks of the solution $x$ ranged between 10 and 15 and were almost constant as $N$ increased (although not presented here), implying that the computational costs were affected mostly by the convergence of the local algorithm. In addition, it should be noted that the computational costs for solving the square linear systems as illustrated in Figure 16 were lower than the costs for the preconditioner computation in Figure 15(a).

5. Conclusion and Discussion. We presented a new MALS algorithm for the computation of approximate pseudoinverses of extremely large-scale structured matrices using low-rank TT decomposition. The proposed method can estimate the Moore-Penrose pseudoinverses of any nonsymmetric or nonsquare structured matrices in low-rank matrix TT format approximately, so it can be useful for preconditioning overdetermined or underdetermined large-scale systems of linear equations.

The proposed method provides stability and the fast convergence speed even for very ill-conditioned large-scale matrices by regularization. The regularized solutions were shown to have relatively small TT-ranks in the numerical simulations, so the computational costs for the construction of preconditioners and solution to huge systems of linear equations were significantly smaller than without regularization. The regularization technique is especially important when the size of a data matrix is huge and ill-conditioned.

The proposed algorithm converts the large-scale minimization problem into sequential smaller-scale optimization problems to which any standard optimization methods can be applied. The convergence to the desired solution is stable and relatively fast because the TT-ranks of the approximate inverses can be adaptively determined during the iteration process, and the decrease in the objective function value is monotonic. The computational cost for running the proposed MALS algorithm is logarithmic in the matrix size under the assumption of boundedness of TT-ranks.

The estimated pseudoinverses were applied to preconditioning of the strongly
nonsymmetric matrix occurring in systems of linear equations in the convection-diffusion equation problem. Several standard iterative algorithms such as GMRES, Bi-CGSTAB, and PCG showed the improved convergence in the numerical simulations, which demonstrate the effectiveness of the proposed algorithm by preconditioning and symmetrizing the coefficient matrix.

The main advantage of the proposed method lies in its applicability to any rectangular huge structured matrices. Moreover, the regularization technique employed in the proposed method helps to compute approximate pseudoinverses reliably for any ill-conditioned structured matrices which admit low-rank TT approximations.

The developed algorithm can further be directly applied to the following areas. First, the computation of regularized Moore-Penrose pseudoinverses is closely related to the regularized (filtered) solution of systems of linear equations $Ax = b$, by $\hat{x} = P^*\lambda^b$, where $P^* \approx A^\dagger$ [7, 8]. Second, the large scale generalized eigenvalue decomposition (GEVD) problem described by $Ax = \lambda B x$ for a square matrix $A$ and a nonsingular square matrix $B$ [21] can be transformed to a standard eigenvalue decomposition problem $B^{-1}Ax = \lambda x$ if the large-scale inverse matrix $B^{-1}$ can be approximately computed in TT format efficiently. Once the large-scale matrices $A$ and $B^{-1}$ are represented in TT format, the multiplication $B^{-1}A$ can be relatively easily performed [41]. Third, a special case of the optimization problem (3.10) arises in important subspace clustering problems [54], which can also be efficiently solved using the proposed algorithm based on TT decompositions.
