Objective: To examine the effect of electroacupuncture on the urodynamics and gut microbiota of rats with stress urinary incontinence (SUI).

Materials and methods: Thirty 2-month-old female Sprague–Dawley (SD) rats were randomly assigned to 4 groups: normal (N), model (M), nonacupoint electric acupuncture control (NAAC), and electroacupuncture (EA). An SUI rat model was established through vagina balloon dilatation and bilateral oophorectomy. After various treatments, urodynamic tests were performed, and feces were collected. 16S rRNA sequencing analysis was used to investigate SUI-related changes in the intestinal flora.

Results: After treatment, compared with those of the M group, the leak point pressure and maximum bladder capacity of the electroacupuncture groups increased (P<0.05). The species community compositions of the N and M groups differed at the genus level, and there were 15 differentially abundant bacterial genera (P<0.05). The Blautia proportion was increased by electroacupuncture treatment (P<0.05) and was significantly positively correlated with the electroacupuncture treatment of SUI (according to Spearman correlation analysis).

Conclusion: Electroacupuncture treatment can improve signs of urine leakage in rats with SUI rats by increasing the leak point pressure and maximum bladder capacity. The enrichment of Blautia by electroacupuncture treatment enrichment may be related to SUI sign improvement.

Introduction

Stress urinary incontinence (SUI) often occurs in middle-aged and elderly women. When abdominal pressure increases, involuntary urine leakage occurs (1). SUI is closely related to vaginal delivery. Vaginal delivery is one of the main causes of SUI and can affect the pelvic muscles, nerves and connective tissues, resulting in insufficient bladder neck and urethral support (2), external urethral sphincter (EUS) and pudendal nerve injury (3). If the endopelvic fascia of the urethra and bladder fascia and the anterior wall of the vagina are damaged, the force of the vagina compressing the urethra will be weakened, resulting in the involuntary outflow of urine when the abdominal pressure increases. EUS and pudendal nerve injury result in EUS weakness and involuntary leakage of urine. Electrical stimulation of the pudendal nerve can promote nerve regeneration and function in rats with SUI (4). The lack of estrogen after menopause changes the metabolism of connective tissue and reduces the production of collagen, which may lead to the occurrence of SUI (5). Studies have shown that estrogen receptors are located in the vagina, urethra, bladder and pelvic floor muscle tissue. The lack of estrogen after menopause is related to the thinning of the submucosa and atrophic changes in the pelvic floor myofascial structure. Atrophic changes in the structure lead to a decrease in the closure pressure of the urethra, which in turn promotes the occurrence of SUI (6, 7). Bladder dysfunction and bowel dysfunction commonly cooccur in clinical practice. Other studies have shown that anal sphincter tears caused by levator ani injury during vaginal delivery are closely related to the development of fecal incontinence (FI) (8). The pudendal nerve also innervates the external anal sphincter. Lower urinary tract symptoms and FI sometimes occur concurrently (9). Electrical stimulation of the pudendal nerve can increase the pressure of the anal sphincter and improve FI symptoms (10).

Some data from experimental animal and human studies have shown that lower urinary tract and intestinal disorders usually occur at the same time (11). A healthy intestinal microbiota can promote individual nutritional metabolism, intestinal mucosal growth and other functions and is related to individual health (12). For example, microbial populations that reside in the gut and other functions and is related to individual health promote individual nutritional metabolism, intestinal mucosal occurrence at the same time (11). A healthy intestinal microbiota can shown that lower urinary tract and intestinal disorders usually.

Materials and methods

Animals and study design

Thirty normal healthy female SD rats weighing 220-250 g were purchased from Beijing Vital River Laboratory Animal Technology Co., Ltd. All rats were provided free access to food and water, maintained under a 12-h light/dark cycle, and randomly assigned to 4 groups: N (n = 6), M (n = 8), NAAC (n = 8), and EA (n = 8). All rats except the N group underwent vaginal balloon dilatation and bilateral oophorectomy to replicate the SUI model (15). Briefly, after anesthesia (sodium pentobarbital, 30 mg/kg, i.p.), an 8-Fr latex Foley catheter was inserted into the rat’s vagina, and 4.0 ml of sterile saline was slowly pushed into the balloon to expand the vagina. The catheter was sutured and fixed, and a 120 g weight was suspended in the drooping injection port. The catheter was removed after 4 hours of traction, and both ovaries were excised with a midline incision after establishing the model.

In the experiment, two urodynamic measurements were made (to reduce the discomfort of the rats, the measurements were made after anaesthesia): one week after modeling and one day after the end of treatment. After emptying the bladder, a 0.7 mm epidural catheter was inserted 2 cm into the rat bladder before fixing it. One end was connected to a microinjection pump through a three-way connector to the bladder, and sterile saline was injected at a speed of 0.3 ml/min. One end was connected to a urodynamic testing instrument (Bonito urodynamic detector, Laborie Medical Technology Company of Canada). The urodynamic testing instrument was calibrated to “0”, and the test was started. When the first drop of fluid appeared at the urethral orifice, perfusion was stopped. At this time, the bladder capacity (perfusion time multiplied by perfusion speed) and intravesical pressures were recorded to determine the leak point pressure (LPP) and maximum bladder capacity (MBC). The sneeze test was carried out after the first urodynamic measurement (16). The success models (n = 17) were randomly assigned to 3 groups: the M (n = 5), NAAC (n = 6), and EA (n = 6) groups.

Treatment protocol

After the first urodynamic measurement, the N and M groups did not receive any treatment. The EA group was treated by electrical stimulation (density wave, 4/20 Hz, 20 min) at the acupoints of Shenshu (BL23, on both sides of the spinous process on the lower back) and Huiyang (BL35, positioned almost vertically underneath the periosteum...
approximately 5 mm lateral to the midline of the coccyx, bilateral symmetry), determined relative to their anatomical locations described in the WHO guidelines for human acupoints (17). A disposable acupuncture needle (diameter, 0.25 mm) was connected to an SDZ-V EA instrument (Shanghai, China). EA treatment was performed once a day and continued for 3 d. For the NAAC group, stimulation was at the Shenshu control point (1 cm beside Shenshu) and at the Huiyang control point (1 cm beside Huiyang). The stimulation settings were the same as in the EA group. The second urodynamic measurements were made after the above treatments. Rat stool samples were collected and stored, and 16S rRNA sequencing was performed to analyze the changes in SUI-related intestinal flora.

### DNA extraction and PCR amplification

After the experiment, 1-2 stool samples each from 4 rats randomly selected from each group were collected using the Omega kit (Omega Bio-Tek, Norcross, GA, U.S.). For DNA extraction, a NanoDrop 2000 was used to assess the DNA purity and concentration, and agarose gel electrophoresis was used to assess DNA integrity. The primers 338F (5′-ACTCCTACGGGAGGCAGCAG-3′) and 806R (5′-GGACTACHVGGGTWTCTAAAT-3′) were used for PCR amplification of the V3-V4 variable region of 16S RNA as follows: denaturing at 95°C for 30 s, annealing at 55°C for 30 s, and extension at 72°C for 30 s for 27 cycles, and a final extension at 72°C for 10 min (PCR instrument: ABGeneAm p(®) 9700). The amplification reaction consisted of 4 µl of 5x Fast Pfu buffer, 2 µl of dNTPs at 2.5 mM, 0.8 µl of primer (5 µM), 4 µl of Fast Pfu polymerase, and 10 ng of DNA template.

### Illumina Miseq sequencing

Samples were sequenced and analyzed on an Illumina MiSeq platform (Illumina, San Diego, USA) according to the standard protocols by Majorbio Bio-Pharm Technology Co., Ltd. (Shanghai, China). The raw reads were quality controlled with Trimmomatic protocols by Majorbio Bio-Pharm Technology Co., Ltd. (Shanghai, China). The raw reads were quality controlled with Trimmomatic software, and FLASH software was used for read assembly. Operational taxonomic units (OTUs) were identified at a 97% similarity cutoff using UPARSE (version 7.1, http://drive5.com/uparse/), and chimeric sequences were identified and removed. The taxonomy of each representative OTU sequence was analyzed by RDP Classifier (http://rdp.cme.msu.edu/) against the 16S rRNA database (Sila SSU132) using a confidence threshold of 0.7.

### Data analysis

Data were analyzed with GraphPad Prism 6.0. One-way analysis of variance (ANOVA) was used to assess the difference between groups, followed by pairwise comparison using the least significant difference (LSD) test. *P* < 0.05 indicated that the difference was statistically significant. The measured data are expressed as the mean ± SEM. The rarefaction curves and alpha diversity indices referring to community richness (Chao1) and community diversity (Shannon) were based on the OTU information. The species composition is represented in a histogram. Diversity among groups was shown by the phylogenetic beta diversities calculated by partial least squares discriminant analysis (PLS-DA) with unweighted UniFrac distances. ANOSIM/Adonis analysis was used to determine whether the grouping was meaningful by testing if the difference between groups was significantly greater than those within groups. Based on a normalized relative abundance matrix, the linear discriminant analysis (LDA) effect size (LEfSe) method based on the Kruskal–Wallis test was used to identify potential biomarkers. The LDA threshold was 2.0, and the significance α was 0.05.

### Results

#### EA improves LPP and MBC in rats with SUI

The effect of EA on LPP in rats with SUI is shown in Figures 1A, B. Before treatment (Figure 1A), compared with that of the N group (78.83 ± 1.40), the LPPs of the M (55.40 ± 1.29), NAAC (59.83 ± 2.13), and EA groups (62.00 ± 2.50) decreased (*P* < 0.05). After treatment (Figure 1B), the LPP of the M group (58.20 ± 2.15) was significantly lower than that of the N group (78.17 ± 2.27) (*P* < 0.05), and the LPP of the rats with SUI increased significantly after EA treatment (73.50 ± 2.32) (*P* < 0.05), while there was no significant difference between the NAAC group (62.17 ± 1.54) and the M group (*P* =0.607>0.05). Similarly, the effect of EA on MBC in rats with SUI is shown in Figures 1C, D. Before treatment (Figure 1C), compared with that of the N group (1.21 ± 0.11), the MBCs of the M (0.76 ± 0.07), NAAC (0.60 ± 0.06), and EA groups (0.81 ± 0.10) decreased (*P* < 0.05). After treatment (Figure 1D), the MBC of the M group (1.08 ± 0.05) was significantly lower than that of the N group (1.58 ± 0.24) (*P* < 0.05), and the MBC of the rats with SUI increased significantly after EA treatment (1.50 ± 0.08) (*P* < 0.05), while there was no significant difference between the NAAC (1.11 ± 0.06) group and the M group (*P* =1.000>0.05).

### Diversity of the microbial community associated with the rats in each group

MiSeq high-throughput sequencing was used to analyze 4 groups of rat stool samples. The alpha exponential rarefaction curve of the Chao1 index (Figure 2A) and the Shannon index...
Figure 2B showed clear asymptotes, which indicated near-complete sampling of the community. Violin plots of the Chao index (Figure 2C) and the Shannon index (Figure 2D) exhibited no significant differences among the four groups. According to ANOSIM/Adonis analysis (R = 0.4721, P = 0.001 < 0.05) and PLS-DA (Figure 2E), there was a significant difference in the species community composition among the groups.

Composition of rat microbial flora between the treatment groups

Figure 3A shows the OTU clustering results detailing the relative abundances of the bacterial community at the genus level in each group of rat stool samples. We found that the dominant bacteria in the N group and the EA group were the same, namely, Bacteroides and norank_f_Muribaculaceae. However, the mean proportions were different. Figure 3B shows the top 15 species with the most abundant expression at the genus level, in which the relative abundance of blautia is statistically different among groups (\*0.01 < P < =0.05, **0.001 < P < =0.01). The comparison of the relative abundance of blautia in rats of each group is shown in Figure 3C. Blautia accounted for 6.68%, 0.37%, 1.36% and 2.52% of the microbial communities of the N group, M group, NAAC group and EA group, respectively, indicating that the content of Blautia increased after EA treatment. Electroacupuncture stimulation can significantly increase or decrease the relative abundance of blautia in Sui rats, but electroacupuncture control group can not reverse this change. Further analysis of 15 different bacteria in the N and M groups at different taxonomic levels by LEfSe (Figure 4) revealed that the relative abundances of the Allobaculum and A2 genera in the M group increased, while the relative abundances of Bacteroides, Bacteroidaceae, Blautia, f_norank_o_Rhodospirillales,
norank_o_Rhodospirillales Anaerostipes, g_Ruminiclostridium_1, g_Candidatus_Soleaferrea, g_GCA_900066225, Erysipelatoclostridium, Holdemania, Burkholderiaceae, and g_Marvinbryantia decreased (LDA = 2.0, P<0.05).

The relationship between microbial flora and urodynamics in rats

Spearman correlation analysis of a heatmap showed the relationship between microbial flora and urodynamics (Figure 5). The bacterial genera positively correlated with MBC were the Lachnospiraceae NK4A136 group and Ruminococcaceae UCG-014. The bacterial genera positively correlated with LPP were Blautia, Ruminococcus_torques_group and Prevotellaceae_Ga6A1_group, while Parabacteroides, norank_f_Lachnospiraceae and Coprococcus_2 were negatively correlated with LPP. The results of Spearman correlation analysis for the N, M, and EA groups are shown in Table 1. The treatment of SUI rats in the EA group was positively correlated with the relative abundance of the genera Blautia and Prevotellaceae_NK3B31_group in terms of the MBC, LPP and sneezing experiments and negatively correlated with the relative abundance of Parabacteroides.
Discussion

The pathogenesis of SUI is mainly related to an increase in the amount of matrix metalloproteinase-degraded collagen in the extracellular matrix of the pelvic floor support tissues, which weakens the muscle support of the urethra and urethral supporting tissues, resulting in the involuntary outflow of urine when the abdominal pressure increases (18–20). Some studies have shown that increased expression of matrix metalloproteinases is accompanied by intestinal inflammation, and there is a relationship between the composition of the microbiome in the intestine and muscle mass (21, 22). Our previous studies have shown that electroacupuncture can improve the degree of SUI by slowing down the degradation of collagen in the anterior vaginal wall of pelvic floor supporting tissue in SUI rats (23). Our study found that EA treatment changed the species composition of the intestinal flora in rats with SUI. Whether there is a link between the influence of EA on intestinal flora and the regulation of collagen metabolism is still unknown.

Aerobic exercise can increase the relative abundance of Bacteroides in the intestinal flora of menopausal women. The increase in Bacteroides abundance is related to the improvement in blood sugar and lipid metabolism and is positively correlated with cardiopulmonary function (24, 25). Bacteria maintain a complex and generally beneficial relationship with the host when...
FIGURE 5
Correlation analysis between urodynamics and different genera. Correlation analysis between MBC, LPP and the major genera. The analysis was conducted using Spearman’s test. Red represents a positive correlation, and blue represents a negative correlation; the deeper the color is, the stronger the correlation (*0.01< P ≤0.05, **0.001 < P ≤0.01).

FIGURE 4
The LDA score identified the size differentiation between the N and M groups with a threshold value of 2. *0.01< P ≤0.05. The relative abundances of the Allobaculum and A2 genera in the M group increased, while the relative abundances of Bacteroides, Bacteroidaceae, Blautia, f._norank_o_Rhodospirillales, norank_o_Rhodospirillales Anaerostipes, g_Ruminiclostridium_1, g_Candidatus_Soleaferrea, g_GCA_9000666225, Erysipelatoclostridium, Holdemania, Burkholderiaceae, and g_Marvinbryantia decreased (LDA = 2.0, P <0.05).
retained in the gut, but when they escape this environment, they
can cause different degrees of pathological changes. On the one
hand, Bacteroides, as a symbiont, has the following functions: (1)
decomposition of complex polysaccharides through a starch
utilization system, (2) T-cell activation via zwitterionic
polysaccharides, and (3) prevention of pathogen colonization
in the gastrointestinal tract (26). On the other hand, Bacteroides,
as a pathogen, includes the Bacteroides protein BVU, the N-
terminal domains 4064 and bf1687 of which may participate in
adhesion interactions to mediate multiple actions on the cell
surface or extracellular matrix (27). For example, Bacteroides
fragilis can not only bind to type I collagen through the collagen
binding protein (CBP1) gene encoding adhesive collagen (28)
but also convert plasminogen in plasma into plasmin through
the outer membrane protein bfp60 to increase the degradation of
fibrin and collagen (29). We found that the proportion of Blautia
in rats with SUI increased after EA treatment, and the relative
abundance of Blautia was positively correlated with the change
in LPP after EA. Blautia species are thought to be important
players in human health based on the correlation between
Blautia abundance and various health conditions, including
diminished abundance in the elderly (30) and in patients with
colorectal cancer (31). Blautia abundance was found to be
negatively correlated with visceral fat accumulation in
adults (32).

In conclusion, EA at the “Shenshu” and “Huiyang” points
can increase LPP and MBC in rats with SUI. We found that
multiple bacterial genera in the intestinal microbial genera of
rats differed between the N group and the M group. Among
them, Blautia was significantly positively correlated with the
effect of EA treatment of SUI. However, whether the effect of EA
on the intestinal microbiota of rats with SUI is related to the
decrease in collagen degradation remains to be clarified in
future studies.

Data availability statement
