Determinación de las temperaturas cardinales de germinación de la espinaca de mameluco (Silybum marianum L.)

Resumen

La respuesta de las plantas a la temperatura es un tema importante. El objetivo de este estudio fue determinar las temperaturas cardinales de las diferentes variedades de espinaca de mameluco (Shomal, Mollasani y Majarestan) expuestas a seis temperaturas constantes (10, 15, 20, 25, 30 y 35 °C) en un diseño completamente casualizado. Los resultados indican que la temperatura y la variedad tienen un efecto significativo en el máximo porcentaje de germinación (MGP), uniformidad de germinación (GU), tasa de germinación (GR), root mean square error (RMSE), coeficiente de determinación (R²), coeficiente de variación (CV), base temperatura (T₀), temperatura de cálculo (T₀), límite inferior de temperatura óptima (Tₕ), temperatura de cálculo (Tₚ), temperatura de calefacción (Fo), tiempo biológico (Tₚb), porcentaje de germinación máximo (MGP), uniformidad de germinación (GU), tasa de germinación (GR), tiempo de radicación (RMSE) y emergence.

Palabras clave: modelo beta, temperaturas cardinales, biología del tiempo, milka, fenología

Introducción

La espinaca de mameluco (Silybum marianum L.) es uno de los cultivos más importantes de los piensos en el mundo, y se usa en el cultivo de los flavonoides de la silimarina, que está activo en la síntesis y el metabolismo del cuerpo. El origen de esta planta ha sido reportado en el área del Mediterráneo Oriental.1 En este siglo, se ha desarrollado un estudio intensivo en el campo de la medicina, y las plantas que contienen ingredientes activos naturales han abierto nuevas perspectivas para el campo de la medicina. Por lo tanto, el campo de la medicina y la investigación agrícola de los países con el objetivo de que los estudios se centren en el cultivo y la producción de medicina.

Este estudio fue desarrollado para determinar los modelos de germinación no lineales para describir la respuesta de germinación de la espinaca de mameluco a la temperatura, y para estimar las temperaturas cardinales de su germinación.
predicting germination. Plant growth rate increases with temperature rises from the base to the optimum temperatures and declines from the optimum to the ceiling temperatures. Temperature not only affects germination percentage but also germination rate. Since temperature has considerable effects on germination characteristics, such as the start of percentage and germination percentage and rate, it is, therefore, the most critical factor determining the success or failure of plant establishment.

Seeds of different plants respond to temperature differently. Germination rate and percentage reach their maximums at the optimum temperatures and decline to zero at the ceiling and the base temperatures. Some studies suggest that, normally, germination rate increases linearly, at least in a suitable temperature range, but falls sharply at temperatures exceeding this range. It is useful to study seed germination and emergence responses to temperature because it allows us to determine the cardinal temperatures for creating models that can predict seed germination and emergence and for selecting the suitable planting time. It also enables us to select species and genotypes that are able to tolerate low or high temperatures and to determine geographical regions where plant species and genotypes can germinate and establish successfully.

Models play an important role in structuring data and ideas, and can determine the weak areas, and the gaps, in our knowledge. A plant model is a mathematical description of our understanding concerning plant behavior and, since mathematics is used in the creation of the model, it must be completely clear and specified at all stages. Therefore, some researchers have used these models to obtain the cardinal temperatures, that is, the base, the optimum, and the ceiling temperatures. There are various functions for describing germination rate responses to temperature, among which three have been used more often: the segmented, the beta, and the dent-like functions.

Kamkar et al. in their study of poppy by using non-linear regression models, recommended the segmented model as the superior model for predicting germination rate. Kamkar et al. also used segmented and logistic models to determine cardinal temperatures of germination in 3millet varieties and emergence in wheat cv. "Tajan". Jame et al. used the beta model in their study on quantification of germination and emergence of spring wheat. Khalilif also used non-linear regression models to quantify germination rate responses of barley to temperature and to water potential, and recommended the beta model as the superior one. Ghaderi-Far et al. in their evaluation of non-linear regression models for the three medicinal plants of pumpkin, brago and black cumin, concluded that the dent-like model described germination rate responses to temperature better than other models.

Materials and methods

This experiment was conducted at the laboratory of Seed Research of Gorgan University of Agriculture and Natural Resources in 2012 using a factorial arrangement of treatments and randomized complete block design in four replications. The experimental treatments included three cultivars of milk thistle (Shomal, Mollasani, and Majarestan) and six levels of temperature (10, 15, 20, 25, 30 and 35 degrees centigrade). Incubators with the accuracy of 0.5 degree centigrade were used for the temperature treatments. Each experimental unit consisted of a petri dish (9-cm diameter) in which 50 milk thistle seeds were placed on top of two sheets of filter paper and were covered by a single sheet of filter paper. Subsequently, depending on the temperature used, the numbers of germinated seeds at different time intervals were counted. Obviously, this interval will be shorter for temperatures closer to the optimum one. At each interval, the germinated seeds were removed. The criterion for germination was a radical emergence of two millimeters or more. Counting was stopped when no seeds germinated within 48 hours, or when all the seeds had germinated. Each time the germinated seeds were counted, the exact time of counting was recorded. During the experiment, distilled water was added to the petri dish when required.

The GS-2011 software (Kamkar, 2011) was used to extract the deciles of germinations. The software fitted seed germination data from these temperature regimes to the logistic function and performed the necessary calculations through interpolation. Moreover, germination rate (per hour) was determined by using formula 1:

$$GR = \frac{1}{D_{50}} \ldots$$ (1)

In the above formula, GR is the germination rate and $D_{50}$, the time it takes for 50 percent of the seeds to germinate.

In this study, three temperature functions were compared to describe changes in germination rate against temperature. These functions were:

1. The Beta function, shown by the abbreviation B, is as follows:

$$f(T) = \left(\frac{T - T_o}{T_o - T_b}\right) \left(\frac{T - T_o}{T_o - T_a}\right) \alpha$$ (2)

2. The Dent-like function, shown by the abbreviation D, is as follows:

$$f(T) = \begin{cases} \frac{\left(T - T_o\right)}{\left(T_o - T_b\right)} & \text{if } T_b < T \leq T_o \\ \frac{\left(T - T_o\right)}{\left(T_o - T_c\right)} & \text{if } T_o < T \leq T_c \\ 1 & \text{if } T_o < T \leq T_o \end{cases}$$ (3)

$$f(T) = 0 \text{ if } T \leq T_o \text{ or } T \geq T_c$$

3. The Segmented function, shown by the abbreviation S, is as follows:

$$f(T) = \begin{cases} \frac{\left(T - T_b\right)}{\left(T_o - T_b\right)} & \text{if } T_b < T < T_o \\ \frac{1 - \left(\frac{T - T_o}{T_c - T_o}\right)}{\left(\frac{T - T_o}{T_c - T_o}\right)} & \text{if } T_o < T < T_c \\ 0 & \text{if } T \leq T_b \text{ or } T \geq T_c \end{cases}$$ (4)

Citation: Heidari Z, Kamkar B, Sinaki JM. Determination of cardinal temperatures of milk thistle (Silybum marianum L.) germination. Adv Plants Agric Res. 2014;1(5):172–178. DOI: 10.15406/apar.2014.01.00027
In the above function, $T_b$ is the base temperature, $T_o1$ the lower limit of optimum temperature, $T_o2$ the upper limit of optimum temperature, $T_c$ the optimum temperature, $T_f$ the biologic temperature, $F_o$ the biologic time, “$a$” a constant coefficient, and $T$ the average daily temperature (the temperature at which the experiment was conducted).

Parameters of each model were estimated by a method of iterative optimization with the help of the PROC NLIN procedure of the SAS software. In this method of iterative optimization, every time the initial values of the parameters are entered, the final value is estimated by the least-squares method. Initial values are changed until the best estimate of the parameters is obtained. The root mean square of errors (RMSE) of germination time, the coefficient of determination ($R^2$), the correlation coefficient ($r$), the simple linear regression coefficients $a$ and $b$, and the relationship between the observed and the predicted germination rates were used to select the superior model from among the employed methods.

The higher the coefficient of determination ($R^2$) is, the higher the percentage of changes in germination rate explained by the model. Coefficients “$a$” and “$b$” represent the degree of deviation of the regression line from the origin of coordinates and the bias of the regression line from the 1:1 line, respectively. The SAS software determined the numerical values of coefficients “$a$” and “$b$.” Significance of coefficient “$a$” was investigated by SAS and that of coefficient “$b$” by determining confidence limits. If coefficient “$a$” is significant, it means that the y-intercept of the regression line and the y-intercept of the 1:1 line do not coincide. If coefficient “$b$” is significant, it means that the slopes of the regression line and that of the 1:1 line are different and that the regression line is biased, in relation to the 1:1 line. The less the points are scattered around the 1:1 line, the more efficient the model is. Given these criteria, the superior model was used to determine the cardinal germination temperatures for describing germination rates of various milk thistle varieties.

**Results and discussion**

Results of analysis of variance of mean squares of maximum germination percentage (MGR), of germination uniformity (GU), of germination rate (GR), and of the time of reaching 5% (D5), 10% (D10), 50% (D50), 90% (D90) and 95% (D95) germination showed that the effects of temperature on all of the mentioned parameters were significant at the one percent probability level. Varieties did not affect the parameter of reaching 5% germination, but had significant effects on the time of reaching 50% and 90% germination at the one percent level of probability and exhibited significant effects on other parameters at the five percent level of probability. Moreover, the mutual effects of variety and temperature on the parameter of germination uniformity at the one percent level of probability, and on the parameter of reaching 90% germination at the five percent level of probability, were significant (but these mutual effects did not significantly influence the other parameters) (Table 1). Nadjafi et al. studied 11 medicinal plant species and reported that the maximum percentage and rate of milk thistle germination were obtained in the temperature range of 10-30 degrees centigrade. The reduction in germination percentage and rate at non-optimal temperatures can be attributed to the reduction or inhibition of enzymatic activity and, hence, to a reduction in the required rates of biosynthetic reactions that necessary for germination at these temperatures. It is expected that high temperatures cause seed deterioration in addition to reducing germination rate.

The beta and the segmented models estimate the base, the optimum, and the ceiling temperatures and the biological time, while the dent-like model estimates the range of optimum temperatures (from the lower limit of optimum temperature to the upper limit of optimum temperature). The criteria used in comparing different models for selecting the superior one to be used in describing germination responses to temperature in various varieties of milk thistle include root mean square of error (RMSE), the coefficient of determination ($R^2$), the regression coefficients “$a$” and “$b$”, and the relationship between the observed germination rate and the predicted one (Table 2).

**Results obtained from comparison of these criteria are as follow:**

In the Shomal variety, the “$b$” coefficient (the bias of the regression line from the 1:1 line) was not significant in any of the three models, and its value in the beta model (0.97) was closer to one compared to the other two models. Moreover, the “$a$” coefficient (the degree of deviation of the regression line from the origin of the coordinates) in the beta and dent-like models was not significant, but it was significant in the segmented model at the five percent probability level. The coefficient “$a$” in the beta model (0.0003) was closer to zero compared to the other two models. The coefficient of determination ($R^2$) in the beta model (99%) was higher compared to the other two models. The root mean square error (RMSE) and the coefficient of variation (CV) in the beta model (0.0006 and 3.9 respectively) were less compared to the other two models (Table 2). The points around the 1:1 line were less scattered in the beta model compared to the other two models. Taking the above points into consideration, and since the “$a$” coefficient was significant in the segmented method, this model was eliminated in the selection of the superior model for the Shomal variety. The root of mean square error, the coefficient of variation, and the scattering of the points around the 1:1 line were lower in the beta model compared to the dent-like model. Therefore, the beta model was selected as the superior model for the Shomal variety and was used in later stages to determine the cardinal temperatures (Figure 1).

In the Mollasani variety, the “$b$” coefficient (the bias of the regression line from the 1:1 line) was not significant in any of the three models, and its value in the beta model (0.99) was closer to one compared to the other two models. Moreover, the “$a$” coefficient (the degree of deviation of the regression line from the origin of the coordinates) in the beta and dent-like models was not significant, but it was significant in the segmented model at the five percent level of probability. The “$a$” coefficient in the beta model was 0.00007 and closer to zero than in the other two models. The coefficient of determination ($R^2$) in the beta model (99%) was higher compared to the other two models (Table 2). The root mean square error (RMSE) and the coefficient of variation (CV) in the beta model (0.0003 and 3.72, respectively) were less compared to the other two models. The points around the 1:1 line in the beta model was less scattered compared to the other two models. Considering the above points, and because the “$a$” coefficient was significant in the segmented model, this model was eliminated in the selection of the superior model. The root of mean square error, the coefficient of variation, and the scattering of points around the 1:1 line were less, and the coefficient of
determination was higher, in the beta model compared to the dent-like model. Therefore, the beta model was selected as the superior model for the Mollasani variety and was used in later stages to determine the cardinal temperatures (Figure 2).

In the Majarestan variety, the “b” coefficient (the bias of the regression line from the 1:1 line) in none of the three models was significant, and its value in the beta model (0.99) was closer to one compared to the other models. Moreover, the “a” coefficient (the degree of deviation of the regression line from the origin of the coordinates) was not significant in any of three models, and its value in the beta model (~ 0.000006) was closer to zero compared to the other two models. The coefficient of determination (R²) in the beta and segmented model, 99%, was higher compared to the dent-like model. The root mean square error (RMSE) and the coefficient of variation (CV) in the beta model (0.0004 and 3.27 respectively) were less compared to the other two models (Table 2). The points around the 1:1 in the beta model were less scattered compared to the other two models. The root mean square error, the coefficient of variation, and the degree of the scattering of the points around the 1:1 lines were less, and the coefficient of determination was higher in the beta model compared to the other two models. Therefore, considering what was earlier said, the beta model was selected as the superior model for the Majarestan variety too, and was used in later stages to determine the cardinal temperatures (Figure 3).

Since the beta model was selected as the superior model for all three studied varieties, its parameters including the base, the optimum, and the ceiling temperatures were used for all three varieties. Based on obtained results:

The estimated base temperatures were 0.00000001, 0.0602, and 0.00000001 degree centigrade for the Shomal, the Mollasani, and the Majarestan varieties, respectively. The estimated optimum temperature for the Shomal variety was 28.79 degrees centigrade, and the Majarestan variety too, and was used in later stages to determine the cardinal temperatures (Figure 2).

For all three varieties was 40 degrees centigrade. Moreover, the biological time for 50% germination was equivalent to 43.61, 42.61, and 45.85 hours for the Shomal, Mollasani, and Majarestan varieties, respectively (Table 3).

Researchers have reported the cardinal temperatures of many plants. Nadjaﬁ et al.,24 in a study on cardinal temperatures of germination of 11 medicinal plants, reported that the base, optimum, and ceiling temperatures for milk thistle (Silybum marianum) were 2.7, 18 and 40.3 degrees centigrade, respectively. In cornflower (Centaura benedicta), they were 0, 13, and 35.5, in hyssop (Hyssopus officinalis) 0, 17.8 and 44.6 in marrubium (Marrubium vulgare) 4, 17.8 and 42.6, and in raceme catnip (Nepeta catarious), 1.3, 24.1 and 42.6 degrees centigrade. The cardinal temperatures were 3.4, 22.5 and 42.5 degrees centigrade in common evening primrose (Oenothera biennis), 4, 23.2 and 41.3 in basil (Ocimum basilicum), 1, 18.4 and 40.1 in marjoram (Origanum majorana). The cardinal temperatures were 0, 21 and 40.3 degrees centigrade in sage (Salvia scarea), 0, 17 and 41 in sage (Salvia nemorosa), and 3.1, 22.7 and 42.4 degrees centigrade in thyme (Thymus daenensis subsp. Daenensis). Kamkar et al.,25 in a study they conducted on poppy, found its base, optimum and ceiling temperatures for germination were 3.02, 27.36 and 36.31 degrees centigrade, respectively. Jami Al-Ahmadi et al.,26 in their research on finding the cardinal temperatures of germination in the species kochia (Kochia scoparia), reported that it could germinate in a wide range of temperatures from 3.5 (the base temperature) to 50 (the ceiling temperature), with its optimum germination temperature being 24 degrees centigrade. Zeinali et al.,27 studied germination in 12 wheat varieties and reported their optimum temperatures varied from 31.8 to 32.4, and their ceiling temperatures from 38.1 to 42.1 degrees centigrade. Jame et al.,28 showed in their study that the base, optimum and ceiling temperatures for wheat were 0, 30 and 42 degrees centigrade, respectively. Khalili29 studied germination in barley and found the base, optimum, and ceiling temperatures were -0.09, 27.5 and 35.7 degrees centigrade, respectively.

Conclusion

Our research showed that of the three common non-linear regression models for quantifying the effects of temperature on germination rate in the three varieties of Shomal, Mollasani, and Majarestan (the beta, the dent-like, and the segmented models), the beta model fitted the observed data best. Therefore, it was selected as the superior model and was used in the determination the cardinal temperatures of germination (the base, the optimum, and the base temperatures). Consequently, the beta model and the parameters estimated by it may be utilized in creating and evaluating predictive models of germination. These parameters can be saved in data banks of various varieties to be used in determining their cardinal temperatures of germination. Results of our research indicated that, in the studied varieties, there were no great differences between the curves showing responses to temperature, and this makes us more confident in using the obtained values, coefficients and biological time.
