(Dated: July 18, 2011)

We perform a finite size scaling study of the three-dimensional Heisenberg spin glass in the presence of weak random anisotropic interactions, up to sizes $L = 32$. Anisotropies have a major impact on the phase transition. The chiral-glass susceptibility does not diverge, due to a large anomalous dimension. It follows that the anisotropic spin-glass belongs to a Universality Class different from the isotropic model, which questions the applicability of the chirality scenario.

I. INTRODUCTION

Spin glasses (SG’s) are disordered magnetic alloys, widely regarded as paradigmatic complex systems.\textsuperscript{1} The degree of anisotropy in the magnetic interactions determines whether a particular alloy is classified as a Heisenberg or an Ising SG (Ising corresponds to a limit of strong anisotropy). Experimentally, anisotropies affect significantly the glassy response to external magnetic fields and the behavior under cooling protocols.\textsuperscript{2}

Theorists have privileged the study of the Ising limit, in spite of the fact that canonical SG’s, e.g. CuMn or AgMn, should be rather regarded as Heisenberg, with weak anisotropic interactions. Indeed, complications arise in the Heisenberg case. In addition to the standard SG ordering, Heisenberg systems show as well a chiral-glass (CG) phase, where chiralities order\textsuperscript{3} (chiralities, also named vorticities, reflect the handedness of the non-collinear spin ordering pattern, see definitions below).

Probably motivated by failures in early numerical attempts\textsuperscript{4} to find a standard SG phase for Heisenberg systems, Kawamura proposed a chirality scenario, expected to hold for most experimental systems.\textsuperscript{5} In the ideal, fully isotropic case, the standard SG critical temperature $T_{\text{SG}}$ would be strictly zero, while chiralities would order at $T_{\text{CG}} > 0$ (spin-chirality decoupling). Yet, anisotropic interactions (either dipolar, pseudo-dipolar or Dzyaloshinskii-Moriya\textsuperscript{6,7}), albeit small, are unavoidable in experimental samples. Hence, the scenario includes a decoupling-recoupling hypothesis: weak random anisotropic interactions would recouple spins and chiralities so that $T_{\text{CG}} = T_{\text{SG}} > 0$. Indeed, the numerical work available at the time indicated that very small amounts of anisotropy lead to $T_{\text{SG}} > 0$.\textsuperscript{8}

CG ordering may be experimentally investigated through the anomalous Hall effect. Due to spin-orbit interaction and the spin polarization of the conduction electrons, the anomalous Hall resistivity picks contributions proportional to the CG order parameter and to its corresponding non-linear susceptibility.\textsuperscript{9,10} The effectiveness of this tool to study non-coplanar orderings has been demonstrated in manganites\textsuperscript{11} and in a geometrically frustrated pyrochlore ferromagnet.\textsuperscript{12}

The effect of anisotropies on the critical behavior was considered by Bray and Moore\textsuperscript{13} before the question of chiral ordering was raised. They predicted that these systems belong to the Ising SG’s Universality Class, no matter the kind of anisotropic interactions. However, in their analysis the assumption was made that $T_{\text{SG}} = 0$ in the isotropic limit (this assumption seemed plausible at the time, although we now know that it is incorrect).

Recent theoretical work has shown that the chirality scenario needs some revision. New simulation algorithms (allowing to thermalize at lower temperatures than pioneering work\textsuperscript{14}), combined with modern finite-size scaling (FSS) methods\textsuperscript{15,16} have provided conclusive evidence for a standard SG ordering with $T_{\text{SG}} > 0$ for purely isotropic interactions.\textsuperscript{17,18} Only some controversy remains on whether $T_{\text{SG}}$ is slightly smaller than $T_{\text{CG}}$,\textsuperscript{19} or rather the two are compatible within errors.\textsuperscript{20} Interestingly enough, a modern-styled study seems to be still lacking for the more realistic case of a Heisenberg SG with small random anisotropy.

Here we show that small anisotropic interactions cause that, at variance with the ideal case, the CG susceptibility no longer diverges at $T_{\text{CG}}$ (i.e. the anomalous dimension becomes $\eta_{\text{CG}} > 2$). In the Renormalization Group framework\textsuperscript{21} anisotropy is a relevant perturbation. Even if in an experimental sample anisotropies are fairly small, the isotropic model is appropriate only for moderate correlation length. Closer to the critical temperature, a new fixed point rules (presumably in the Ising SG Universality Class, due to spin-reversal symmetry). A slow crossover\textsuperscript{15} from the Heisenberg to the anisotropic fixed-point arises upon approaching the phase transition. We conjecture that this crossover explains\textsuperscript{22} experimental claims of a non-trivial dependency of critical exponents on the anisotropy strength.\textsuperscript{23} Our results follow from a FSS analysis of equilibrium Monte Carlo simulations on system-sizes up to $L = 32$. Data suggest that anisotropies cause a temperature range in which chiralities order while spins do not (i.e. $T_{\text{SG}} < T_{\text{CG}}$). However, due to the slow crossover, further research will be needed to dismiss spin-chirality recoupling.
The remaining part of this work is organized as follows. We define the model and describe our numerical methods in Sect. II. We address thermal equilibration, a major issue in any spin-glass simulation, in Sect. III. Our physical results are reported in Sect. IV. Finally, we give our results in Sect. V.

II. MODEL AND SIMULATIONS

Since the main types of anisotropic interactions lead to the same effective replica Hamiltonian, it is numerically convenient to study short range (pseudo-dipolar) interactions. Take the Edwards-Anderson model on a cubic lattice of size L, with periodic boundary conditions. Heisenberg spins occupy the lattice nodes \( x \) [\( \vec{S}_x = (S^x_1, S^y_1, S^z_1), \vec{S}_y = (S^x_2, S^y_2, S^z_2) \), \( \vec{S}_x \cdot \vec{S}_x = 1 \)]. The Hamiltonian is

\[
H = -\sum_{(x,y)} \left( J_{xy} \vec{S}_x \cdot \vec{S}_y + \sum_{\vec{e}} D_{xy} \vec{S}_x \cdot \vec{S}_y \right),
\]

(\( (x, y) \): lattice nearest-neighbors). The random exchange-couplings, \( J_{xy} \), are Gaussian distributed with \( \langle J_{xy} \rangle = 0 \), and \( \sum_{y} J_{xy} = 1 \). The random \( D_{xy} \) are \( 3 \times 3 \) symmetric matrices (i.e. \( \vec{S}_x \cdot D_{xy} \vec{S}_y = D_{xy} \vec{S}_x \cdot \vec{S}_y \)). Their matrix elements are independent and uniformly distributed in \((-D, D)\). In most of the work reported here \( D = 0.05 \) (which corresponds to the best studied case\(^2\)), but we will be presenting results for \( D = 0.1 \) as well.

The ideal limit of a fully isotropic Heisenberg model is recovered from Eq. (1) by setting \( D = 0 \). Once \( D > 0 \), the original O(3) symmetry, corresponding to a global spin rotation (or reflection), is lost. The only remaining symmetry for \( D > 0 \) is global spin inversion.

An instance of the couplings, \( \{ J_{xy}, D_{x,y}^\mu \} \) is named a sample. For any physical quantity, we first obtain the thermal average, denoted as \( \langle \ldots \rangle \). Only afterwards we perform the sample average (denoted by an overline).

Defining the SG and CG susceptibilities requires real replicas. We consider pairs of spin configurations, \( \vec{S}_x^a \) and \( \vec{S}_y^a \), that evolve with independent thermal noise, under the same couplings and at the same temperature. The spin-overlap field is \( q_x = \vec{S}_x^a \cdot \vec{S}_x^b \), while its Fourier transform at wave vector \( \vec{k} \), is \( \tilde{q}_{SG}(\vec{k}) = \sum_{x} q_x e^{i\vec{k} \cdot \vec{x}} / N \). On the other hand, the local chirality is defined as:

\[
\zeta_{\mu} = \vec{S}_x e_\mu \cdot (\vec{S}_x \times \vec{S}_y - e_\mu), \quad \mu = 1, 2, 3,
\]

where \( e_\mu \) is the unit lattice vector along the \( \mu \) axis. From \( 2\), the chiral overlap-field is \( \kappa_{\mu} = \zeta_{\mu} a^b \cdot e_\mu \), where the superindices \( a \) and \( b \) correspond to the replicas. Its Fourier transform is \( \tilde{q}_{CG}(\vec{k}) = \sum_{\mu} \kappa_{\mu} e^{i\vec{k} \cdot \vec{x}} / N \).

The wave-vector dependent susceptibilities are:

\[
\chi_{SG}(\vec{k}) = N \langle |\tilde{q}_{SG}(\vec{k})|^2 \rangle, \quad \chi_{CG}(\vec{k}) = N \langle |\tilde{q}_{CG}(\vec{k})|^2 \rangle.
\]

III. EQUILIBRATION

We considered three thermalization tests. First, consider the identity (valid for Gaussian-distributed \( J_{x,y} \)):

\[
\Delta \equiv \frac{q_x - q_y}{T} + \frac{2}{z} U = 0,
\]

where \( U = -\sum_{(x,y)} J_{x,y} \vec{S}_x \cdot \vec{S}_y / L^D \), the link-overlap is \( q_l = 2 \sum_{(x,y)} (\vec{S}_x \cdot \vec{S}_y / L^D \vec{S}_y / (zL^D) \), while \( q_s =

EMCS×10^3 & 3 & 3 & 1.8 & 3.6 &
\end{array}
\]

Table II: As in Table I for our simulations with \( D = 0.1 \).

The correlation length, either SG or CG, is\(^{15,25} \)

\[
\xi = \left( \frac{1}{2 \sin(k_{\text{min}}/2)} \left( \frac{\chi(0)}{\chi(k_{\text{min}})} - 1 \right) \right)^{1/2},
\]

where \( k_{\text{min}} = (2\pi/L, 0, 0) \) or permutations.\(^{26} \)

Our simulation algorithm combines heat-bath with microcanonical overrelaxation.\(^{22} \) Both moves generalize straightforwardly to the anisotropic case.\(^{28} \) The mixed algorithm is effective for the isotropic Heisenberg SG\(^{17,20,29} \) and for other frustrated models.\(^{20} \) Besides, we extrapolate to nearby temperatures using a bias-corrected\(^{24} \) data reweighting method.\(^{22} \) Most of our simulations were carried out with \( D = 0.05 \), see Table I. Nevertheless, we did as well as possible for \( D = 0.1 \), see Table II.
2 \sum_{(x,y)} \langle (\vec{S}_x \cdot \vec{S}_y)^2 \rangle / (z L^D) \quad (z = 6 \text{ is the lattice coordination number}). Now, both \( U \) and \( q_t \) equilibrate easily. Yet, since \( q_t \) involves two replicas, it slowly grows from zero until its equilibrium value. Thus, a thermalization bias shows up as \( \Delta > 0 \). The time evolution of \( \Delta \), for \( L = 32 \) at the lowest \( T \), is in Fig. 1. Second, we carried out the standard logarithmic data binning: we compare averages over the second half of the Monte Carlo history, with the second fourth, the second eight, and so forth, finding stability for three bins. Third, we checked for compatibility among reweighting extrapolations for contiguous temperatures (our simulations at different \( T \) are statistically independent, see Fig. 2).

### IV. RESULTS

Our FSS analysis compares the correlation length in units of the lattice size for pairs of lattices \( (L, 2L) \). Dimensionless quantities, such as \( \xi / L \), are functions of \( L^{1/\nu} (T - T_c) \), \( \nu \) being the thermal critical exponent. Thus, the two curves intersect at \( T_c(L, 2L) \), see Fig. 2. This is to be expected only if \( \eta \geq 2 \). If the susceptibility does not diverge at \( T_c \), the correlation length in Eq. (1) scales as \( \xi / L \sim L^{-(\nu - 2)/2} \). Nevertheless, we still find crossings when comparing lattices sizes \( L \) and \( 2L \), see Fig. 2.

We discuss first the CG sector. The inset of Fig. 2 shows an unusual feature: \( \xi_{CG}/L \) at the crossing point \( T_{CG}(L, 2L) \) approaches zero for large \( L \). This is to be expected only if \( \eta \geq 2 \). If the susceptibility does not diverge at \( T_c \), the correlation length in Eq. (1) scales as \( \xi / L \sim L^{-(\nu - 2)/2} \). Nevertheless, we still find crossings when comparing lattices sizes \( L \) and \( 2L \), see Fig. 2.

### TABLE III: Size-dependent critical temperatures \( T_{SG}(L, 2L) \) and \( T_{CG}(L, 2L) \), and anomalous dimensions \( 2 - \eta_{SG} \) and \( 2 - \eta_{CG} \), Eq. (6), for the simulations with \( D = 0.05 \). Errors were obtained with jackknife.

| \( L \) | \( T_{SG}(L, 2L) \) | \( T_{CG}(L, 2L) \) | \( 2 - \eta_{SG} \) | \( 2 - \eta_{CG} \) |
|---|---|---|---|---|
| 8 | 0.251(2) | 0.187(1) | 2.091(11) | 0.360(5) |
| 8 | 0.235(1) | 0.202(1) | 2.131(9) | 0.223(8) |
| 12 | 0.207(5) | 0.221(1) | 2.413(46) | 0.081(5) |
| 16 | 0.179(10) | 0.233(1) | 2.639(55) | 0.030(5) |

Besides, it is not worthy that, in spite of the smallness of \( D \), \( T_{CG}(L, 2L) \) for \( D = 0.05 \) is about twice its value for the isotropic model, \( T_{CG}(D = 0) \approx 0.13 \). In fact, extrapolating the data in Table III as \( T_{CG}(L, 2L) = T_{CG} + A/L \) yields \( T_{CG} \approx 0.26 \). To further investigate the lacking divergence of \( \chi_{CG} \) at
at factor slower than the standard point-to-point correlations by a factor $r^{D-1}$. The scaling behavior of the integrals $I_k$ is: $I_k \sim constant$ in the paramagnetic phase, $I_k \sim k^{k+2-\eta}$ at $T_{CG}$ (if $k + 2 - \eta > 0$, otherwise it is $I_k \sim constant$), and $I_k \sim L^{D+k}$ in the CG phase. We show in Fig. 4 top our data for $\chi_{CG}$ (which is basically $2I_0$) and, in Fig. 4 bottom, $I_1$. Note that for $T < 0.22$ the two integrals are diverging with $L$. On the other hand, for $T = 0.22, 0.23$, $I_1$ grows with $L$, while $\chi_{CG}$ does not, as expected for $2 < \eta_{CG} < 3$.

The behavior of the SG sector is more conventional. A remarkable feature in Fig. 2 and Table II is the strong scaling corrections in $T_{SG}(L, 2L)$. We do not consider it safe to extrapolate $T_{SG}$ to its large-$L$ limit, as we are far from the asymptotic regime. The SG anomalous dimension takes a negative value as $L$ grows (also found in the Ising SG, see e.g. 23).

An intriguing feature is that $T_{SG}$ seems smaller than $T_{CG}$. Indeed, see Fig. 4 at $T \approx 0.187$, where $\xi_{SG}/L$ becomes $L$-independent, $\xi_{SG}/L$ is growing fast with $L$. Yet, three caveats prevent us from considering this conclusion as definitive: (i) our lattice sizes are still in a strong cross-over regime, hence the final picture could change as $L$ grows, (ii) the behavior is rather marginal, meaning a larger number of samples would be needed to accurately locate $T_{SG}$ (this is hardly surprising, given the large value of exponent $\nu$, and the small $\theta$ exponent, for $d = 3$ Ising SG’s), and (iii) when considering a larger anisotropy, see below, the effect seems smaller.

Indeed, we have performed further simulations with $D = 0.1$, up to $L = 16$. As shown in Fig. 4 the difference between $T_{SG}$ and $T_{CG}$ is less clearly defined than for $D = 0.05$. On the other hand, the chiral-glass susceptibility is not divergent at the critical point, in agreement with our results for $D = 0.05$. Consistently with that, the crossing points for $\xi_{CG}/L$ shift to a smaller height when $L$ grows.

V. CONCLUSIONS

In summary, we have performed a finite size scaling study of the 3d Heisenberg spin glass in the presence of a weak random anisotropy, for lattices of size up to $L = 32$. Anisotropies cause that the CG susceptibility no longer diverges at $T_{CG}$, the chiralities ordering temperature. Hence, the anisotropic system belongs to a Universality Class different from the isotropic model (probably that of Ising SG’s). Besides, we found that the spin-glass ordering sets up only at $T_{SG} < T_{CG}$. The most economic scenario is that actually $T_{SG} = T_{CG}$ (the apparent difference would be due to finite-size effects). In this scenario, chiralities would merely be a composite operator (such as, say, the ninth power of the spin overlap). However, the would-be intermediate temperature region where only chiralities order should be experimentally detectable through the anomalous Hall effect. Numerical studies covering a wider range of values for the anisotropic coupling could also help to elucidate the situation.
ACKNOWLEDGMENTS

We thank A. Tarancon, G. Parisi and P. Young for discussions. Simulations were performed at BIFI (Terminus, 6.6 \times 10^5 hours of CPU time) and Red Española de Supercomputación (Caesar Augusta, 2.79 \times 10^5 hours), whose staff we thank for the assistance provided. We were partly supported by MICINN (Spain) through research contract No. FIS2009-12648-C03, and (S.P.G.) through the FECYT Foundation.

37 For planes parallel to (say) the \( \mu = 3 \) lattice axis, add the correlation function for all pairs of sites \( \vec{x} = (n_1, n_2, n_3), \vec{y} = (m_1, m_2, m_3) \) such that \( m_3 - n_3 = r + kL \), with \( k \) integer, then divide by \( L^D \). We average over the three lattice directions, as well as over the longitudinal (weight 1/3) and the transversal (weight 2/3) correlation functions.
