(Dated: October 29, 2018)

Single photons from a coherent input are efficiently redirected to a separate output by way of a fiber-coupled microtoroidal cavity interacting with individual Cesium atoms. By operating in an overcoupled regime for the input-output to a tapered fiber, our system functions as a quantum router with high efficiency for photon sorting. Single photons are reflected and excess photons transmitted, as confirmed by observations of photon antibunching (bunching) for the reflected (transmitted) light. Our photon router is robust against large variations of atomic position and input power, with the observed photon antibunching persisting for intracavity photon number 0.03 ≲ ν ≲ 0.7.

PACS numbers:

Cavity quantum electrodynamics (cQED) offers systems in which the coherent interaction between matter and light can dominate irreversible channels of dissipation [1, 2, 3, 4]. Diverse systems based upon radiative interactions in cQED are thereby promising candidates for the physical implementation of quantum networks, where, for example, atoms in optical cavities (quantum nodes) are linked by photons in optical fiber (quantum channels) [4]. Although many important capabilities for quantum nodes have been demonstrated within the setting of cQED with single atoms in Fabry-Perot cavities [5, 6, 7, 8, 9, 10], an outstanding challenge is high efficiency transport of quantum fields into and out of optical cavities [11], as is required to link large numbers of quantum nodes.

In this regard, the coupling rate κ of photons to and from the quantum channel should dominate the rates for any other input-output mechanisms. One way to achieve this is to operate the nodes in an overcoupled regime [11], where external coupling dominates internal system losses. In the microwave domain, “circuit QED” systems routinely operate in the overcoupled regime [11] for high external efficiency.

In this Letter, we realize a cQED system in the optical domain with efficient input-output coupling while still maintaining high internal efficiency for coupling to a single atom. We use a microtoroidal cavity interacting with single Cesium atoms [12, 13, 14], with coupling to and from the cavity implemented with a tapered optical fiber in an overcoupled regime [11]. As a proof of principle, we demonstrate an efficient and robust photon router for which single photons are extracted from an incident coherent state and redirected to a separate output with efficiency ξ ≃ 0.6.

To model photon transport for the atom-cavity system, we consider the interaction of one atom with the evanescent fields of a microtoroidal cavity, as shown in Fig. 1(a), with gω the rate of coherent atom-cavity coupling [15]. Near the atomic resonance at frequency ωA, the cavity supports two counter-propagating modes a, b of frequency ωC. These cavity modes have intrinsic loss rate κi and are coupled to each other at rate h (e.g., due to internal scattering) [11]. Input to and output from the internal modes of the cavity are provided by a tapered fiber with external coupling rate κex, where the fields of the tapered fiber are denoted by {aex, bex, ain, aout, bfin, bout}. For single-sided excitation as in our current

FIG. 1: (a) Simple depiction of one atom coupled to a toroidal cavity, together with fiber taper and relevant field modes, with rates (gω, κex, κi, h) as defined in the text. (b-d) Theoretical plots for the parameters of our experiment, (gω, κex, κi, h)/2π = (50, 300, 20, 10) MHz, with ωA = ωC. (b, c) Transmission and reflection spectra T(Δ), R(Δ) for aout, bout as functions of probe detuning Δ = ωC − ωp with and without the atom. (d) Theoretical density correlation functions versus Δ for the transmitted (gR(τ = 0)) and reflected (gR(τ = 0)) fields. (e) Schematic of our experiment. A Cesium MOT is formed in a separate chamber, and atoms are transferred to the main chamber via an optical conveyor belt. Atoms are then dropped onto a toroid, which is coupled to a tapered fiber as in (a). A probe beam ain is injected into the taper, and the transmitted aout and reflected bout fields are measured with two pairs of single-photon detectors D1-4.
The Hamiltonian, master equation, and input-output relations for the system depicted in Fig. 1(a) can be found in Refs. [13, 14, 16]. When the total cavity decay rate, $\kappa = \kappa_i + \kappa_{\text{ex}}$, is much larger than any other rate in the system, the cavity modes can be adiabatically eliminated from the system dynamics [17]. The system can then be described by effective optical Bloch equations for a two-level atom with the cavity-enhanced atomic decay rate $\Gamma = \gamma(a^\dagger b^\dagger b^\dagger + h.c.)$ is the cooperativity parameter for a single atom and $\gamma$ is the rate of atomic decay to modes other than $a, b$.

In the overcoupled regime of toroid-taper coupling, $\kappa_{\text{ex}} \gg (\kappa_i, h)$, the analytic expressions for steady-state transmitted $I_T = \langle a_{\text{out}}^\dagger a_{\text{out}} \rangle_{\text{ss}}$ and reflected $I_R = \langle b_{\text{out}}^\dagger b_{\text{out}} \rangle_{\text{ss}}$ fluxes, and for the second-order correlation functions, $g_2^{(2)}(\tau) = \langle a_{\text{out}}^\dagger b_{\text{out}}^\dagger b_{\text{out}} a_{\text{out}}(\tau) a_{\text{out}} a_{\text{out}} \rangle_{\text{ss}}/I_T^2$ and $g_2^{(2)}(\tau) = \langle b_{\text{out}}^\dagger b_{\text{out}} a_{\text{out}} a_{\text{out}} \rangle_{\text{ss}}/I_R^2$, can be greatly simplified. Specifically, at zero detuning (i.e., $\omega_A = \omega_C = \omega_p$) and in the weak driving limit, the transmission and reflection coefficients are given by [19]

$$T(\Delta = 0) \equiv I_T(0)/I_T(\Delta \gg \kappa) \equiv T_0 \simeq \frac{1}{(2C + 1)^2},$$
$$R(\Delta = 0) \equiv I_R(0)/I_R(\Delta \gg \kappa) \equiv R_0 \simeq \left(\frac{2C}{2C + 1}\right)^2,$$

while second-order intensity correlations at zero time delay are found to be

$$g_2^{(2)}(\tau = 0) \simeq (4C^2 - 1)^2,$$
$$g_2^{(2)}(\tau = 0) \simeq 0.

The physical interpretation of these results is as follows. In steady state and with $C \gg 1$, the field radiated by the atomic polarization $\sigma^{SS}$ interferes destructively with the intracavity field from $a_{\text{in}}$, resulting in small transmission $T_0 \ll 1$. But $\sigma^{SS}$ also coherently drives the intracavity field $b$, thereby generating a backward propagating field $b_{\text{out}}$, leading to reflection $R_0 \rightarrow 1$ [19]. On the other hand, the overcoupled cavity without the atomic polarization (i.e., $C = 0$) has $T_0 \approx 1$ and $R_0 \approx 0$. Strong optical nonlinearity of the atom-toroid system gives rise to a dynamical switching between these two limits conditioned upon photon detection. (1) $T_0 \simeq 0$, $R_0 \simeq 1$ due to the field from $\sigma^{SS}$, and (2) $T_0 \simeq 1$, $R_0 \simeq 0$ due to the conditional atomic polarization $\sigma^C$ following photon detection [19].

This description is substantiated by examination of $g_2^{(2)}(\tau)$. Detection of a ‘first’ photon for the reflected field $b_{\text{out}}$ projects the atom to the ground state, which precludes the detection of a ‘second’ photon for $b_{\text{out}}$ [14, 19]. Hence the reflected light exhibits sub-Poissonian photon statistics and photon antibunching. Similarly, photon detection for the transmitted light $a_{\text{out}}$ results in atomic projection that depends on $\mathcal{E}_p$ and $C$ [19], with then $a_{\text{out}}$ displaying photon bunching and super-Poissonian statistics. The net effect is the routing of single photons into the backward direction $b_{\text{out}}$ and remaining excess photons into the forward field $a_{\text{out}}$.

Figures 1(b-d) present theoretical results for transmission and reflection spectra $T(\Delta)$, $R(\Delta)$ and intensity correlations $g_2^{(2)}(0)$, $g_2^{(2)}(0)$ in the weak-driving limit for the parameters of our experiment: $(g_{\text{tw}}, \kappa_{\text{ex}}, \kappa_i, h)/2\pi = (50, 300, 20, 10)$ MHz. Although not deeply in the overcoupled regime, efficient transmission and reflection can be achieved, with $T_0 \approx 0.005$, $R_0 \approx 0.7$ with an intracavity atom, and $T_0 \approx 0.8$, $R_0 \approx 0.003$ without the atom.

A schematic of our experiment is shown in Fig. 1(e) and is similar to that described in Refs. [13, 14]. However, our new apparatus has two major improvements that allow us to reproducibly tune $\kappa_{\text{ex}}$ to the desired overcoupled value and to maintain a small $\kappa_i$. Firstly, the silicon chip supporting an array of SiO$_2$ toroidal cavities and the tapered fiber for input-output coupling are mounted on piezo-electric-driven stages that are placed inside the main chamber. The combination of compact, rigid design and good passive vibration-isolation enable us to tune the separation between the taper and toroid and to achieve stable coupling between the evanescent fields of the taper and toroid without having the taper contact the surface of the toroid.

Secondly, in order to avoid degradation of quality factor for the toroids caused by Cesium contamination, our new apparatus has a separate “MOT chamber” where Cesium atoms are magneto-optically cooled and trapped, then loaded into an optical conveyor belt [20] and transferred into the “cQED chamber” through a differential pumping tube. The optical conveyor is formed by two counter-propagating beams red detuned 100 GHz below the D2 line of Cesium to form a standing-wave dipole-force trap. By independently shifting the frequencies of each beam with acousto-optic modulators, atoms loaded from the MOT are conveyed 25 cm from MOT to cQED chamber and positioned directly above a particular toroid on the silicon chip.

The resonance frequency $\omega_C$ of the toroid is tuned via the chip temperature near the frequency $\omega_A$ of the 6S$_{1/2}$, $F = 4 \rightarrow 6P_{3/2}$, $F' = 5$ transition of Cesium, with $|\omega_A - \omega_C|/2\pi \approx 30$ MHz. The frequency $\omega_p$ of the probe beam $\mathcal{E}_p$ is locked to coincide with $\omega_A$, with $|\omega_A - \omega_p|/2\pi \approx 1$ MHz. The probe is sent into the taper via the 1% port of 99/1 fiber beamsplitter (Fig. 1(e)). The 99% port of this beamsplitter is connected to a 50/50 beamsplitter followed by two single-photon counting-modules (SPCMs), $D_1, D_2$, to detect the reflected field $b_{\text{out}}$. Similarly, the transmitted field $a_{\text{out}}$ in the taper is detected with another pair of SPCMs,
Physically, the properties of the new toroids for our current experiment are similar to those in Ref. [14]. The major diameter $D \approx 25 \mu m$ and minor diameter $d \approx 6 \mu m$, leading to an effective atom-cavity coupling rate of $g_{eff}/2\pi \approx 70$ MHz ($g_{eff}/2\pi \approx 50$ MHz) [12, 15]. Combined with the measured values for $(\kappa_{ex}, \kappa_1, h)$ and with $\gamma/2\pi = 5.2$ MHz, we calculate the single-atom cooperativity parameter $C = 3.0$ and the cavity-enhanced atomic decay rate $\Gamma/2\pi = 36.4$ MHz. Note that for large toroid-taper separation with $\kappa_{ex} \approx \kappa_1$, our system is in the strong coupling regime of eQED with $g_{eff} > \kappa, \gamma$.

About $10^7$ atoms with temperature $T \approx 100\mu K$ are dropped from a height of 0.5 mm above the toroid by turning off the dipole trap beams. As shown in Fig. 1(c), the reflected intensity $I_R$ associated with $b_{out}$ should be near zero when there is no atom in the cavity. A falling atom that interacts with the evanescent fields of the cavity generates an increase in $I_R$ for the duration of the atomic transit and enables single transit events to be observed with high signal-to-noise ratio [21]. While transiting atoms are sufficient for these experiments due to our insensitivity to atomic position, in the future we recognize the need to trap and localize single atoms near the toroid to allow continuous operation of the system [7, 8, 9, 10].

We first fix the probe power $|E_0|^2$ such that the intracavity photon number $\bar{n} = 0.093$ for the empty cavity. Atom transit events are extracted from the records of photoelectric counts $C_{1,2}(t)$ from $b_{out}$ at detectors $D_1, D_2$ by the following procedure. For an atom transit event, we require the sum of the counts over a time $\Delta t_{atom}$, $S_j = \sum_{t_i=t_{th}}^{t_i+\Delta t_{atom}} [C_1(t_i) + C_2(t_i)]$, to be equal or greater than a threshold count $C_{th}$. After applying this selection criterion to $C_{1,2}(t)$, we determine the time origin $t = 0$ for each transit event by the temporal mean of the counts in $\Delta t_{atom}$ and extract counts in a time window of $\pm 6\mu s$ around $t = 0$ for further analysis.

Figure 2(a,b) show the transmitted $T_0(t)$ and reflected $R_0(t)$ signals averaged over transit events with transit selection criteria of $C_{th} = 5, 6, 7$, and $\Delta t_{atom} \approx 4\mu s$, where $T_0(t)$ and $R_0(t)$ are normalized to the resonant transmission of the empty cavity, $T_0 \approx 0.83$. Atom-cavity coupling results in reduced transmission and increased reflection [22]. The second-order correlation functions $g^{(2)}_{T,R}(\tau)$ for the transmitted and reflected fields $a_{out}, b_{out}$ are calculated in the same manner as in Refs. [14, 15] and plotted in Fig. 2(c,d). Photon bunching and antibunching are clearly observed for $a_{out}, b_{out}$ in the forward and backward directions, respectively. The recovery time $\tau_R$ to steady state is set by the cavity-enhanced atomic decay rate $\Gamma = \gamma(1+2C)$, with $\tau_R \sim 1/\Gamma$ [14, 15].

These observations are consistent with the theoretical predictions in Fig. 1(b-d) for $\Delta = 0$, thereby demonstrating a functional photon router. Note that the traces with larger threshold $C_{th}$ show more significant effects of atom-cavity coupling. This is because we have fewer “falsely detected transits” (i.e., time windows that have no atom but nevertheless satisfy the selection criterion $S_j \geq C_{th}$ because of background light) and reduced contributions from transits with smaller $g$.

To explore this point further, in Fig. 3(a) we plot the ratio $F$ of false to total atomic transit events, $F = R_{0}^{th}(t=0)/R_0(t=0)$, where $R_{0}^{th}$ is the measured transit signal for the reflected field as in Fig. 2(b), but now with no atoms present. Clearly, $F$ decreases as $C_{th}$ in-
The solid lines in Fig. 4 are from a simplified theoretical model based on adiabatic elimination of the cavity [10]. The curves are obtained from an average over the atomic azimuthal position $kx$ around the major circumference of the toroid. Curves for particular values of $kx$ would be indistinguishable on the scale of the plot. This insensitivity to $kx$ is due to the small coupling between the counterpropagating modes $a$ and $b$, characterized by the ratio $h/k \approx 0.03 \ll 1$, that limits the formation of a standing wave [10].

To account for background light, the dashed lines in Fig. 4 include background counts at a level of 4% of the signal. This leads to good agreement for the background-sensitive parameter $\gamma_R^{(2)}(\tau = 0)$ in Fig. 4(b). There still remains a discrepancy for $T_0$ in Fig. 4(a) given the statistical error bars, even when we account for variation in $g_{tw}$ by averaging over a range of values around $g_{tw} = 50$ MHz ($g_{tw} = 35$ MHz to $g_{tw} = 65$ MHz). Thus, we must attribute the discrepancy in (a) to a systematic uncertainty in the experiment.

In summary, we have realized a photon router using single Cesium atoms coupled to a microtoroidal cavity in the overcoupled regime. In comparison to our previous photon turnstile [11], this photon router is robust against azimuthal position of the atom ($kx$) and taper-toroid distance ($\kappa_{ex}$), in addition to the atom-cavity coupling strength ($g/\kappa$)). The current system already has throughput efficiency for single photons of $\xi \approx 0.6$ and it is projected to reach $\xi \approx 0.999$ through use of smaller toroid diameter [20] and improvement of the intrinsic quality factor of the cavity to $Q \approx 10^{10}$ [24]. The realization of strong interactions of single photons and atoms together with efficient input-output provides an enabling capability for the realization of quantum networks and investigations of quantum many-body systems built component by component.

For our previous work [13, 14], the taper and toroid were critically coupled with the taper in contact mode. Atom transits were detected as increases in the transmitted intensity $I_T$ for the field $a_{\text{out}}$.

The asymmetry evident in Fig. 2(a,b) is a robust feature of our observations. We have no definitive explanation, but are investigating various possible causes, including surface forces.
