Quantum spin fluctuations provide a unique way to study spin dynamics without system perturbation. Here we put forward an optical resonance shift spin noise spectroscopy as a powerful tool to measure the spin noise of various systems from magnetic impurities in solids to free atoms and molecules. The quantum spin fluctuations in these systems can shift the optical resonances by more than the homogeneous linewidth and produce huge Faraday rotation noise. We demonstrate, that the resonance shift spin noise spectroscopy gives access to the high order spin correlators, which contain complete information about the spin dynamics in contrast with the second order correlator measured by conventional Pauli-blocking spin noise spectroscopy. The high order quantum spin correlators manifest themselves as a comb of peaks in the Faraday rotation noise spectra in transverse magnetic field. This effect is closely related with the multipolar Raman scattering observed in the Mn-doped nanostructures.

I. INTRODUCTION

The quantum spin fluctuations were first predicted by Felix Bloch back in 1946 \cite{1}. With the development of the experimental techniques, the optical spin noise spectroscopy appeared and eventually became a powerful tool for the spin dynamics investigation in a broad class of paramagnetic media, from atomic gases to semiconductors \cite{2, 3}. In typical experiments, the spin fluctuations within the small volume of a paramagnetic material produce a stochastic Faraday rotation of the linearly polarized light, which probes the system, and the spin noise spectra are obtained by the Fourier transformation of the time-dependent Faraday rotation.

In a magnetic field perpendicular to the probe beam, the spin noise spectrum shows peaks at the Larmor frequencies of the studied spins, similar to the optically detected magnetic resonance. Quantum-mechanically the spin noise signal can be considered as a result of the interference of the probe beam with the light emission caused by spin-flip forward scattering of the probe light \cite{4, 5}.

In atomic gases, the dependence of the light scattering amplitude on the spin state of an atom is provided by the Pauli blocking of the optical transitions in certain polarizations, defined by the probed spins orientation. This scenario is also realized for electrons and holes in semiconductors with the pronounced spin-orbit interaction, such as GaAs or CdTe \cite{6}. In the charged quantum dots (QDs), for example, for the electron spin-up or spin-down state the optical transitions to the singlet heavy hole trion state are possible for $\sigma^+$ or $\sigma^-$-polarized light only, respectively. In thermal equilibrium, the number of spin-up and spin-down electrons is the same on average, but stochastic spin fluctuations produce a weak Gaussian Faraday rotation noise, which is measured. This type of experiments can be called “Pauli-blocking spin noise spectroscopy”.

The small Faraday rotation angles in Pauli-blocking spin noise spectroscopy make it difficult to detect the spin correlation functions of the orders higher than two \cite{7, 8}. In the same time, the complete information about the spin dynamics including its intrinsic quantum properties can be obtained from the complete set of the spin correlators of all orders only \cite{9–11}. As a minimal extension of the standard theories the weak measurements of the third and fourth order spin correlators were described \cite{12, 13}.

An alternative connection between the spin system and the light polarization is realized in diluted magnetic semiconductors \cite{14}. In this case the probed spins belong to the d-shell electrons of Mn$^{2+}$ ions, embedded into the crystal lattice. Mn atoms do not create localized charge carrier states, and their spins do not affect interband optical transitions directly. However, their spins are coupled to the spins of the conduction electrons and holes by the $sp – d$ exchange interaction. The corresponding coupling constant is very large, of the order of 1 eV. Due to this interaction, fluctuations of the magnetic ions modulate the energies of the interband optical transitions (most often involving localized excitons), and this creates a polarization noise of the probe light, so we call this type of experiments “resonance shift spin noise spectroscopy”. Atomic-like hyperfine structure of Mn$^{2+}$ spin levels was resolved in such experiments with the very diluted CdMnTe quantum wells in weak magnetic fields \cite{15}. The same mechanism is responsible for the observation of the nuclear spin noise in GaAs \cite{16, 17}. Moreover the resonance shift spin noise spectroscopy can be applied to any impurities in the semiconductors or to the spins of nuclei of free atoms and molecules.

The general arguments, which followed the first Pauli-blocking spin noise measurement \cite{4} establish the relation between the spin noise spectrum and the spin flip Raman spectrum. In the case of the resonance shift spectroscopy, this relation apparently breaks down. Indeed, there exists a phenomenon of the multipolar Raman scattering, when the resonant Raman spectrum of Mn doped nanostructures shows a comb of peaks up to 15 equally spaced peaks \cite{18, 19}. These spectra are explained by the
scattering via the virtual magnetic-polaron states, and the observed phenomenon is therefore essentially quantum [20, 21]. On the other hand, the Larmor precession of the spin fluctuation of one, several or many Mn$^{2+}$ ions induces the peak in the spin noise spectrum at the single Larmor frequency only, and not at its multiplies.

In this work, we show that the multiplet spin Raman scattering is a counterpart of the high order quantum spin noise spectra, which can be observed by means of resonance shift spin spectroscopy in semi-magnetic structures. We develop a general theory of the resonance shift quantum spin noise spectroscopy and describe in a unified way the spin noise and Raman spectra. We demonstrate, that the shape of the spectra is different for the thermal and quantum spin noise. Detection of the high order spin correlators allows one to completely describe the spin dynamics, and to distinguish between Gaussian and non-normal spin fluctuations. In particular, we show that for deep impurities in semiconductors and in atomic systems the spin noise spectra strongly differ from the Gaussian noise spectra.

The paper is organized as follows: In Sec. II we present a model and derive the general expression for the Faraday rotation noise spectrum in the framework of the resonance shift spin noise spectroscopy. In what follows, we focus on the semimagnetic quantum wells and QDs, where we anticipate the fastest experimental measurement of the higher order spin correlators. In Sec. III we establish the relation between the Faraday rotation noise and Raman spin-flip spectra in different polarizations. In Sec. IV we calculate and describe the spectra for the Gaussian spin noise and in Sec. V we describe the non-normal spin noise. Finally, we discuss the applications of our theory to the different spin systems from the solid state to free atoms and summarize our findings in Sec. VI.

II. MODEL

As a model system for the resonance shift spin noise spectroscopy we consider a II-VI semiconductor doped with manganese. The spins of Mn$^{2+}$ atoms can be optically monitored via a localized exciton resonance. We assume, that the excitons are localized at defects, in QDs, or at imperfections of the interfaces of a quantum well. The general form of the Hamiltonian is

$$
\hat{H}(t) = \hat{H}_0 + \hat{H}_{\text{exc}} + \hat{H}_{\text{int}} + \mathcal{V}(t). \quad (1)
$$

Here $\hat{H}_0$ is the Hamiltonian of Mn$^{2+}$ spin system, $\hat{H}_{\text{exc}}$ is the exciton Hamiltonian, $\hat{H}_{\text{int}}$ describes the interaction between exciton and Mn$^{2+}$ spins, and $\mathcal{V}(t)$ stands for the coherent optical excitation of excitons.

The spin dependent part of the interaction of magnetic atoms with excitons stems from the exchange interaction with electron and hole in the exciton. The general form of this interaction is [22]

$$
\hat{H}_{\text{int}} = \hbar \sum_i \omega^e_{\text{ex},i} \hat{S}_{\alpha}^{e} \hat{I}_i + \sum_{\alpha} \omega^{h,\alpha}_{\text{ex},i} \hat{S}_{\alpha}^{h} \hat{I}_{i,\alpha}, \quad (2)
$$

where $i$ enumerates Mn$^{2+}$ spins $\hat{I}_i$, $\hat{S}_{\alpha}^{e}$ and $\hat{S}_{\alpha}^{h}$ are the electron and hole spins in the given exciton, respectively, $\omega^e_{\text{ex},i}$ and $\omega^{h,\alpha}_{\text{ex},i}$ are the corresponding exchange interaction constants with the Cartesian index $\alpha = x, y, z$. Due to the different symmetry of the electron and hole Bloch wave functions in the $\Gamma$ valley, the electron exchange interaction is isotropic, while for the heavy hole it is not. This anisotropy plays an important role for this system, and has the same origin as the anisotropy of the effective $g$-factor.

We consider the optical detection of Mn$^{2+}$ spins by resonant laser probe light, which is described by the term

$$
\mathcal{V} = -\hat{P}^\dagger \mathcal{E} e^{-i \omega_{\text{p}} t} + \text{H.c.}, \quad (3)
$$
in the Hamiltonian (1). Here $\mathcal{P}$ is the dipole moment operator (in Schrödinger representation), $\omega_{\text{p}}$ is the probe frequency and $\mathcal{E}$ is the amplitude of the incident electric field. The probe light induces an exciton dipole polarization, which is described by the Heisenberg time dependent operator $\hat{P}(t)$. In Appendix A we demonstrate, that it has the form $\hat{P}(t) = \hat{P} \psi(t)$, where $\psi(t)$ is a dimensionless operator, which satisfies the transparent equation

$$
\frac{d\psi(t)}{dt} = \frac{i}{\hbar} \hat{P}^\dagger \mathcal{E} e^{-i \omega_{\text{p}} t} - \frac{i}{\hbar} \left[ \hat{H}_{\text{exc}} + \hat{H}_{\text{int}}(t) \right] \psi(t) - \gamma \psi(t). \quad (4)
$$

Here we introduced the interaction Hamiltonian in the interaction representation

$$
\hat{H}_{\text{int}}(t) = e^{i \hat{H}_{\text{tot}} t/\hbar} \hat{H}_{\text{int}} e^{-i \hat{H}_{\text{tot}} t/\hbar} \quad (5)
$$

and an optical transition dephasing rate $\gamma$. The equation (4) can be formally integrated, and the result for the time dependent exciton polarization reads

$$
\hat{P}(t) = \frac{i}{\hbar} \mathcal{P} \int_0^\infty e^{-i \omega_{\text{p}} (t - \tau)} \gamma d\tau \times \mathcal{T} \exp \left[ -\frac{i}{\hbar} \int_0^\tau \hat{H}_{\text{exc}}(\tau - \tau') d\tau' \right] d\tau \left( \hat{P}^\dagger \mathcal{E} \right). \quad (6)
$$

Here $\mathcal{T}$ exp denotes the normal time ordered exponential (later times on the left) and $\hat{H}_{\text{exc}}(t) = \hat{H}_{\text{exc}} + \hat{H}_{\text{int}}(t)$ is an effective time dependent exciton Hamiltonian. It is this part of the expression that contains information about parameters of Mn$^{2+}$ spin dynamics ($\hat{H}_0$). The obtained general expression allows one to describe various physical systems and experimental conditions. Below we consider a specific case, when this expression is greatly simplified.
interaction strength with the random spin components is not weak, and the electron Zeeman energy exceeds the spin does not change. This means, that the magnetic field does not change.

Second, we assume, that the transverse hole -factor, which is usually very small [23].

We focus on the Voight geometry, when external magnetic field is applied along $z$ direction, perpendicular to the optical axis $z$. The $Mn^{2+}$ spin Hamiltonian takes a form

$$\mathcal{H}_0 = \hbar \Omega_L I_x,$$  

where

$$I = \sum_{i=1}^{N} I_i (8)$$

is the total spin of $N$ Mn atoms in the exciton localization volume and $\Omega_L = g\mu_B B/\hbar$ is the Larmor precession frequency in the magnetic field $B$ with $g$ being the $g$-factor and $\mu_B$ being the Bohr magneton. We assume the Mn concentration to be small enough to neglect their exchange interaction. This corresponds to the Mn concentration of a few percent or less.

We stress, that we consider here the optical transitions to the localized exciton state, while other types of transitions, e.g., to the trion or to the biexciton state can be described in a similar way. Let us make some other simplifying assumptions, which make the theory transparent and the results very illustrating. First, we neglect the transverse hole $g$-factor, which is usually very small [23]. Second, we assume, that the $x$ projection of the electron spin does not change. This means, that the magnetic field is not weak, and the electron Zeeman energy exceeds the interaction strength with the random spin components $I_{i,x}$ and $I_{i,z}$. In fact, $Mn^{2+}$ spins can be partially polarized along the magnetic field at low temperatures, and can create the effective exchange magnetic field along the same direction, which can exceed the external magnetic field for electrons. Below for simplicity we consider only one electron spin state (say, $S_z = +1/2$). This implicitly assumes, that the splitting of the electron spin sublevels exceeds the homogeneous and inhomogeneous widths of the optical resonance. Under these assumptions we arrive to the optical V-scheme, which is shown in Fig 1. Here the exciton vacuum state $|g\rangle$ can be excited by $\sigma^+$ of $\sigma^-$ polarized light to the exciton state with the heavy hole spins $J_z = \pm 3/2$, respectively.

Without the exchange interaction with the magnetic impurities the two excitonic states are degenerate, so the exciton Hamiltonian reads

$$\mathcal{H}_\text{exc} = \hbar \omega_0 n_{\text{exc}},$$

where $\omega_0$ is the resonance frequency and $n_{\text{exc}}$ is the occupancy of the both exciton states. The exchange interaction leads to the splitting of the two resonances, which we describe by

$$\mathcal{H}_\text{ex} = \hbar \omega_{\text{ex}} 2/3 \hbar \gamma z I_z.$$  

Here we neglect the total shift of the two resonances due to the exchange interaction with electron ($\omega_{\text{ex},i} = 0$) and consider the hole exchange interaction along the $z$ axis only [22]. Also for the simplicity we use the box model and set equal exchange interaction constants for all $Mn^{2+}$ spins: $\omega_{\text{ex},i} = (2/3)\omega_{\text{ex}} \delta_{i,z}$.

Under these assumptions, the two excitonic states are not mixed. As a results, the circularly polarized $\sigma^\pm$ probe light induces the exciton dipole polarization with the same helicity

$$P_{\pm}(t) = \pm (P_{z}(t) - i P_{y}(t))/\sqrt{2}.$$  

From Eq. (4) we find, that

$$\frac{dP_\pm(t)}{dt} = -i [\omega_0 \pm \omega_{\text{ex}} I_z(t) - i \gamma] P_\pm(t) + \frac{i}{\hbar} |d|^2 E_\pm(t) e^{-i\omega_p t},$$

where $d$ is the optical transition dipole moment (see Appendix A). This equation clearly shows, that the spin polarization $I_z(t)$ shifts the exciton resonance energy $\omega_0$, which allows one to optically monitor $Mn^{2+}$ spin fluctuations. In fact, it follows from Eqs. (5) and (7), that $I_z(t) = \cos(\Omega_L t) I_z + \sin(\Omega_L t) I_y$, but we prefer to keep the general notation $I_z(t)$, which is valid for arbitrary spin Hamiltonian $\mathcal{H}_0$.

In the specific system under study, the general expression (6) for the polarization reduces to

$$P_{\pm}(t) = \frac{i}{\hbar} |d|^2 E_\pm e^{-i\omega_p t} \int_0^\infty e^{i(\omega_p - \omega_0) \tau - \gamma \tau} \times \mathcal{T} \exp \left[ \mp i \omega_{\text{ex}} \int_0^\tau I_z(t - \tau') d\tau' \right] d\tau.$$  

Here the inner integral can be solved as described in Appendix A, but for the calculation of the spectra of the secondary emitted light this expression is more convenient.

It is useful to analyze this expression in the adiabatic approximation. Provided $\Omega_L \ll \gamma$ the Mn spin dynamics...
is slow as compared with the exciton polarization relaxation. In this case one can replace $I_z(t - \tau')$ with $I_z(t)$ and solve the ordered exponential. Then the outer integral can be solved as well, which yields

$$P_{\pm}(t) = \frac{|d|^2 E_{\pm}}{\hbar} \frac{e^{-i\omega_{\pm} t}}{\omega_0 \pm \omega_x I_z(t) - \omega_p - i\gamma}. \quad (13)$$

This expression shows that: (i) Mn spin polarization shifts the exciton resonance frequency, and (ii) the relation between Mn spin polarization and the exciton dipole polarization is nonlinear. The latter makes it possible to detect high order spin correlators using the resonance shift spin spectroscopy. Crucially, $I_z(t)$ should be considered here as the Heisenberg operator. Only when $I$ is a large classical vector, the corresponding operator can be replaced with its expectation value.

### III. GENERAL RELATIONS BETWEEN SPIN CORRELATION FUNCTIONS AND RESONANCE SHIFT OPTICAL RESPONSE

The spin noise spectra are typically measured using the linearly polarized light,

$$E = E_0 e_x, \quad (14)$$

where $E_0$ is an amplitude of the probe light, and $e_x$ is a unit vector along $x$ axis. The optical Faraday and ellipticity signals, $F$ and $E$, respectively, are measured in the transmission or reflection geometry. They are given by the real and imaginary parts of the equality [24]

$$F - iE = E_x' E'_y. \quad (15)$$

Here $E'$ is the amplitude of the emitted (or scattered) light. It consists of the contribution from the elastic scattering and the secondary emission by the exciton dipole polarization:

$$E' = aE + bP, \quad (16)$$

where $a$ and $b$ are complex coefficients, which depend on the geometry of the structure [17]. In the next section we calculate the Faraday rotation noise spectra, which can be detected using the resonance shift spin spectroscopy.

The Faraday rotation angle of the probe polarization plane and the ellipticity angle can be calculated as

$$\theta_F - i\theta_E = \frac{F - iE}{I}, \quad (17)$$

where $I = |E'_y|^2$ is proportional to the intensity of the detected light. These expressions assume that the angles are small $\theta_{F,E} \ll 1$ or equivalently $|E'_y| \ll |E'_x|$. Usually the scattering is weak, $bP_x \ll aE_0$, so by virtue of Eq. (16) we arrive to

$$\theta_F + i\theta_E = \frac{E'_y}{E'_x} = \frac{b}{aE_0} P_y. \quad (18)$$

This expression shows that the spin signals are proportional to the exciton polarization along $y$ axis.

The optical signals noise spectra are defined as the Fourier transform of the correlation functions:

$$\langle \theta_{F,E}^2 \rangle_s = \int_{-\infty}^{\infty} \langle \theta_{F,E}(t)\theta_{F,E}(t + \tau) \rangle_s e^{i\Omega \tau} d\tau. \quad (19)$$

Here the angular brackets denote quantum mechanical averaging and the subscript “s” denotes the symmetrized correlator

$$\langle \theta(0)\theta(\tau) \rangle_s = \frac{\langle \theta(0)\theta(\tau) + \theta(\tau)\theta(0) \rangle}{2}. \quad (20)$$

In the steady state, the averages do not depend on time $t$, so for the rest of the paper we set $t = 0$ in the correlation functions. The symmetrization is related with the fact, that the detected light is almost classical and the optical spin signals are self-homodyned [25–27]. From Eqs. (19) and (18) one can see, that the Faraday and ellipticity noise spectra are determined by the Fourier transform of the correlation functions of the components of the exciton polarization. In Pauli-blocking spin noise spectroscopy this correlator is simply proportional to the spin noise spectrum. However, in the case of the resonance shift spin noise spectroscopy, there is no direct relation between them.

In the same time the Raman spectrum of the scattered light in polarization $\alpha$ is given by

$$S_{\alpha\alpha}^{\text{tot}}(\omega) = \int_{-\infty}^{\infty} \langle E_{\alpha}^*(t)E_{\alpha}(t + \tau) \rangle \exp{i\omega \tau} d\tau. \quad (21)$$

In the general case the Raman spectrum consists of a $\delta$-peak at $\omega = \omega_p$, which does not carry information about the spin system, and the rest of the spectrum $S(\omega)$. It can be presented as

$$S(\Omega + \omega_p) = |b|^2 \int_{-\infty}^{\infty} \langle P_{\alpha}^*(0)P_{\alpha}(\tau) \rangle \exp{i\Omega \tau} d\tau. \quad (22)$$

Thus we arrive again at the Fourier transform of the exciton polarization correlation function.

The exciton polarization is given by Eq. (12), which implicitly depends on Mn$^{2+}$ spin fluctuations. Now let us establish the general relations between the spectra of different polarization components and the multi-order spin correlation functions.

#### A. Spectrum in circular polarization

In this section we consider an auxiliary problem of $\sigma^+$ incident light, so the scattered light has the same polarization, $\alpha = +$. We calculate the spectra of the dimensionless exciton polarization

$$p(t) = -\frac{\hbar \gamma}{|d|^2 E_0} P(t) e^{i\omega_p t}, \quad (23)$$
which in this case are proportional to the Raman spin flip spectrum in $\sigma^+$ polarization, see Eq. (22). The spectrum in $\sigma^-$ polarization is the same.

It is convenient to rewrite Eq. (12) as

$$p_+(t) = \int_0^\infty e^{-i\delta k - k T} \exp [-i\mathcal{J}(t)] dk,$$

(24)

where

$$\delta = (\omega_0 - \omega_p)/\gamma,$$

(25)

is a dimensionless detuning and

$$\mathcal{J}(t) = \int_0^k m(t - k'/\gamma) dk'$$

(26)

with

$$m(t) = \frac{\omega_{ex}}{\gamma} I_z(t)$$

(27)

being a dimensionless splitting of the resonance. Further, we note that for the localized excitons, the inhomogeneous broadening usually exceeds by far the homogeneous one (see, e.g., Ref. 18). Therefore the spin noise and Raman spin flip spectra should be averaged over the detuning as

$$\langle p_+^*(0)p_+(\tau) \rangle = \frac{1}{2\pi} \int_{-\infty}^\infty \langle p_+^*(0)p_+(\tau) \rangle d\delta.$$  

(28)

Here we introduced the factor $1/(2\pi)$ to shorten the following expressions. We substitute here the exciton polarization from Eq. (24) and obtain the averaged correlation function

$$\langle p_+^*(0)p_+(\tau) \rangle = \int_0^\infty e^{-2k} \left[ \mathcal{T} e^{i\mathcal{J}(0)} \left[ \mathcal{T} e^{-i\mathcal{J}(\tau)} \right] \right] dk,$$

(29)

where $\mathcal{T}$ denotes the reversed time ordering. The correlator in this expression can be calculated using the cumulant expansion.

Generally, the quantum noise statistics is completely described by the series of cumulants of the random variable $\omega_{ex}$ in Appendix B we obtain the general expressions for the polarization correlation function and simplify it for the Gaussian spin noise. To obtain a simple expression for the polarization correlator let us consider again the adiabatic approximation, $\Omega L \ll \gamma$. In this case one can replace $m(t - k'/\gamma)$ in Eq. (26) with $m(t)$. Then from Eq. (29) we obtain

$$\langle p_+^*(0)p_+(\tau) \rangle = \sum_{n=0}^{2n} \sum_{l=0}^{2n-l} \binom{2n}{l} \langle m'(0)m^{2n-l}(\tau) \rangle,$$

(30)

where $(\binom{2n}{l})$ is the binomial coefficient. This expression shows, that the polarization correlator and Faraday rotation noise spectra are determined by the spin correlation functions of all orders. Thus, the resonance shift spin noise spectroscopy measures high order spin correlators in addition to the standard second order correlator. This surprising result originates in the nonlinear relation between the exciton polarization and the total Mn$^{2+}$ spin in the limit $I_z \gg 1$ [see, e.g., Eq. (13)].

For Gaussian spin noise using Eq. (B7) we obtain

$$\langle p_+^*(0)p_+(\tau) \rangle = \int_0^\infty e^{-k^2\Delta m^2(\tau)} e^{-2k} dk,$$

(31)

where we introduced

$$\Delta m^2(\tau) = \langle m^2 \rangle - \langle m(0)m(\tau) \rangle.$$  

(32)

This integral can be solved as

$$\langle p_+^*(0)p_+(\tau) \rangle = \frac{1}{2} \sqrt{\frac{\pi}{\Delta m^2(\tau)}} e^{1/2\Delta m^2(\tau)} \text{erfc} \left( \frac{1}{\sqrt{\Delta m^2(\tau)}} \right).$$

(33)

If exchange interaction is weak, $m(t) \ll 1$ one can use the asymptotic expansion

$$\langle p_+^*(0)p_+(\tau) \rangle = \frac{1}{2} \sum_{n=0}^\infty \frac{\Delta m^2(\tau)}{2} (2n - 1)!!.$$  

(34)

This expression directly relates the spin correlation function $\Delta m^2(\tau)$ with the polarization correlator.

### B. Faraday rotation noise spectra and Raman spectra in linear polarizations

Let us return to the linearly polarized probe light, Eq. (14). Similarly to Eq. (24), the dimensionless exciton polarization in this case reads

$$p_x(t) = \int_0^\infty e^{-i\delta k - k T} \cos [\mathcal{J}(t)] dk,$$

(35a)

$$p_y(t) = -\int_0^\infty e^{-i\delta k - k T} \sin [\mathcal{J}(t)] dk,$$

(35b)

where we introduced the notations

$$\mathcal{T} \cos(x) = \frac{\mathcal{T} e^{ix} + \mathcal{T} e^{-ix}}{2}, \quad \mathcal{T} \sin(x) = \frac{\mathcal{T} e^{ix} - \mathcal{T} e^{-ix}}{2i}.$$  

(36)

Then one can perform the calculations following the lines of the previous subsection: average the correlation function $\langle p_+^*(0)p_+(\tau) \rangle$ over the detuning, express it through the cumulants and in the limit $N \gg 1$ neglect all the cumulants of high orders. For clarity we give the final result for the adiabatic limit [c.f. Eq. (31)].
These expressions along with Eq. (22) allow one to directly calculate the Raman spectrum for the given Mn spin correlation function. Here the integrals can be expressed through the error function, and its asymptotic expansions can be found. However, these expressions are cumbersome, and will not be needed below.

As a first step towards the relation between Raman and spin noise spectra, we consider the Raman spectrum in crossed (y) polarization, where the exciton dipole polarization and Mn spin polarization linear polarizations. In the next section we calculate and obtain

\[
\langle p_y^2(0)p_y(\tau) \rangle = \int_0^\infty d\kappa e^{-2\kappa \langle m^2(\tau) \rangle} \left[ \frac{\text{ch}(\kappa^2 \langle m(0)m(\tau) \rangle)}{\text{sh}(\kappa^2 \langle m(0)m(\tau) \rangle)} \right].
\]  

IV. FARADAY ROTATION NOISE SPECTRUM IN VOIGT GEOMETRY

A. Spin correlation functions

The general expressions (37) relate the Faraday rotation noise and Raman spin flip spectra with the spin correlators. Here we calculate the correlation functions in external magnetic field described by Eq. (7).

The average Mn spin is oriented along \( B \) and equals to

\[
\langle I_x \rangle = N s B_s \left( \frac{g \mu_B B_s}{k_B T} \right),
\]

where \( s = 5/2 \) is a single Mn\(^{2+} \) spin, \( B_s(x) \) is the Brillouin function, \( k_B \) is the Boltzmann constant, and \( T \) is the temperature. Using the commutation relations for the spin components we find also the correlators

\[
\langle I_y I_z \rangle = -\langle I_z I_y \rangle = \frac{1}{2} \langle I_x \rangle \tag{43a}
\]

\[
\langle I_z^2 \rangle = \frac{N}{2} \left[ s(s+1) - \langle s_x^2 \rangle \right]. \tag{43b}
\]

Notably, the first of these two equations is responsible for the quantum part of the spin correlation functions. Indeed, for classical noise the correlation functions do not depend on the order, in which the fluctuating quantities are multiplied. Moreover, Eq. (43b) shows, that even at zero temperature, when \( \langle s_x^2 \rangle = s^2 \), zero-point spin fluctuations \( \langle I_z^2 \rangle = N s^2/2 \) are present.

The time correlation functions for \( \tau > 0 \) obey the equations

\[
\frac{d}{d\tau} \langle I_x(0)I_z(\tau) \rangle = \Omega_L \langle I_x(0)I_y(\tau) \rangle - \frac{\langle I_z(0)I_z(\tau) \rangle}{\tau_s}, \tag{44a}
\]

\[
\frac{d}{d\tau} \langle I_x(0)I_y(\tau) \rangle = -\Omega_L \langle I_x(0)I_z(\tau) \rangle - \frac{\langle I_z(0)I_y(\tau) \rangle}{\tau_s}, \tag{44b}
\]

where \( \tau_s \) is a transverse spin relaxation time (we assume that \( \hbar/\tau_s \ll k_B T \)). The solution of these equations with the initial conditions (43) reads

\[
\langle I_x(0)I_z(\tau) \rangle = \frac{1}{2} \left[ \left( \frac{\langle I_z^2 \rangle}{2} + \frac{\langle I_x \rangle}{2} \right) e^{i\Omega_L \tau} + \left( \frac{\langle I_z^2 \rangle}{2} - \frac{\langle I_x \rangle}{2} \right) e^{-i\Omega_L \tau} \right] e^{-|\tau|/\tau_s}. \tag{45}
\]
Then using the definition (27) we find the dimensionless correlation function
\[
\langle m(0)m(t) \rangle = (\mu_+ e^{-i\Omega_L t} + \mu_- e^{i\Omega_L t}) e^{-|\tau|/\tau_s},
\]
where we introduced
\[
\mu_{\pm} = \frac{\omega_s^2}{2\gamma^2} \left( \langle I_z^2 \rangle \mp \frac{\langle I_x^2 \rangle}{2} \right).
\]
The correlator \(\langle m(0)m(t) \rangle\) ultimately defines the noise spectra of Faraday rotation and ellipticity, which we analyze in the next subsection.

B. Faraday rotation noise and Raman spectra

Similarly to Sec. III it is convenient to start from the analysis of the exciton dipole polarization correlation function in circular polarizations, which define the corresponding Raman spectra.

To shorten the notation we introduce the scaled spectrum [c.f. Eq. (22)]
\[
S_{++}(\Omega) = \int_{-\infty}^{\infty} \left( \langle p_x^2 (0)p_{+}(\tau) \rangle \right) e^{i\Omega\tau} d\tau.
\]
From Eqs. (34) and (46) one can see, that the spectrum consists of the peaks at frequencies \(n\Omega_L\), where \(n\) is an integer. The general form of the spectrum of circularly polarized exciton dipole polarization is
\[
S_{++}(\Omega) = \sum_{n=1}^{\infty} \sum_{\pm} P_n^{\pm}(\Omega = n\Omega_L),
\]
where \(P_n^{\pm}(\Omega)\) are even functions peaked at zero and we neglect the peak at zero frequency.

Another general property follows from the ratio of prefactors in Eq. (46). From the definition (39) (without symmetrization) one can see, that
\[
\frac{\langle I_z^2 \rangle}{\langle I_z^2 \rangle - \Omega_L} = e^{-k\Omega_L/(kB)t}.
\]
Generally, this relation is inherited by the polarization spectra [Eq. (48)] in the form
\[
\frac{S_{++}(\Omega)}{S_{++}(-\Omega)} = e^{-\Omega_L/(kB)t},
\]
which is well known for the Raman spectra.

The Raman spin flip spectra in \(\sigma^+\) and in \(\sigma^-\) polarizations coincide and are given by Eq. (49):
\[
S_{--}(\Omega) = S_{++}(\Omega).
\]
We recall, that the two circular polarizations are independent in the lowest order in the incident electric field, so the cross-polarized spectra in circular polarizations vanish: \(S_{\pm}(\Omega) = 0\).

The Raman spin flip spectra in linear polarizations and Faraday rotation and ellipticity noise spectra can be calculated using Eqs. (37) and (41) for the adiabatic regime. Similarly to Eq. (49) the Raman spectra take the form
\[
S_{xx}(\Omega) = S_{yy}(\Omega) = \sum_{k=1}^{\infty} \sum_{\pm} P_n^{\pm}(\Omega = 2k\Omega_L),
\]
\[
S_{xy}(\Omega) = S_{yx}(\Omega) = \sum_{k=0}^{\infty} \sum_{\pm} P_n^{\pm}(\Omega = (2k + 1)\Omega_L).
\]
The Faraday rotation (and ellipticity) noise spectra are given by
\[
S_{FR}(\Omega) = \frac{S_{xy}(\Omega) + S_{yx}(-\Omega)}{2},
\]
which differs from \(\langle \theta_{xx} \rangle\) and \(\langle \theta_{yy} \rangle\) by a factor.

In the illustrative case of \(m(t) \ll 1\) one can substitute Eq. (45) in the asymptotic Eq. (34), which yields
\[
S_{++}(\Omega) = \sum_{n=1}^{\infty} \sum_{\pm} \frac{(2n-1)!!}{2n} \frac{\mu_n^{\pm}}{1 + [\Omega/n + \Omega_L/\tau_s]^2} e^{-|\tau|/\tau_s}.
\]
One can see, that the spectrum consists of Lorentzian peaks at the frequencies \(\mp n\Omega_L\) with the areas (divided by \(2\pi\))
\[
A_n^{\pm} = \frac{(2n-1)!!}{2n+1} \frac{\mu_n^{\pm}}{2},
\]
respectively. The widths of these peaks are \(n/\tau_s\). We stress, that the second order spin correlation function \(45\) contains the spin precession frequencies \(\pm \Omega_L\) only. Therefore the appearance of the overtones is a fingerprint of the contributions of the higher order spin correlators.

For high order contributions, \(n \gg 1\), Eq. (55) diverges, and the above analysis is inapplicable. Generally, one has to start from Eq. (31), where
\[
\Delta m^2(\tau) = \sum_{\pm} \mu_{\pm} \left( 1 - e^{\mp i\Omega_L \tau} e^{-|\tau|/\tau_s} \right)
\]
according to Eq. (46). Thus we obtain
\[
\frac{\langle p_x^2 (0)p_{+}(\tau) \rangle}{\langle p_x^2 (0)p_{+}(\tau) \rangle} = \int_{0}^{\infty} e^{-2k} e^{-k^2(\mu_+ + \mu_-)}
\]
\[
\times \exp \left[ k^2 \left( \mu_+ e^{-i\Omega_L \tau} + \mu_- e^{i\Omega_L \tau} \right) e^{-|\tau|/\tau_s} \right] dk.
\]
The exponent in the second line can be decomposed in
the Taylor series as

$$
\langle p^*_n(0)p^+(\tau) \rangle = \int_0^\infty e^{-2k} e^{-k^2(\mu_+ + \mu_-)}
\times \sum_{n=0}^\infty \frac{k^{2n}}{n!} \left( \mu_+ e^{-\Omega_L \tau} + \mu_- e^{\Omega_L \tau} \right)^n e^{-n|\tau|/\tau_s} d\Omega.
$$

Again, one can see, that the correlation function contains harmonics $\propto e^{\pm i n \Omega_L \tau}$, so the spectrum consists of the peaks at frequencies $\pm n \Omega_L$.

In Fig. 2 we compare the different spectra in the limit of zero temperature $T = 0$ and strong exchange interaction $\sqrt{N \omega_{ex}} \gg \gamma$. All the spectra show the comb of peaks at frequencies, which are multiples of the Larmor spin precession frequency. The peaks in the Raman spectra correspond to the multiple spin flips mediated by the excitonic state, as shown in the top of the figure. Importantly, multiple spin flips take place in one process due to the RKKY-type exchange interaction between Mn$^{2+}$ spins mediated by the heavy hole spin. The same mechanism can also lead to the double spin flips of donor bound electrons [31] and of electrons confined in the nanoplatelets [32]. In the Faraday rotation noise spectra, the peaks at frequencies $\pm n \Omega_L$ reflect the contributions of quantum spin noise correlation functions of order 2$n$. We recall, that the average spin polarization along $z$ axis is absent, so the correlators of the odd orders vanish. Observation of high order spin correlators is possible due to the nonlinear relation between dipole polarization and the total Mn$^{2+}$ spin. Similarly, noise of the linear birefringence was recently shown to produce the peak at the double Larmor frequency for cesium atoms [33].

The Raman spin flip spectra in Fig. 2 are asymmetric (contain only the peaks at negative frequencies) because the energy can not be absorbed from the zero-point spin fluctuations. Alternatively one can say, that the Mn$^{2+}$ spins are all oriented along $x$ axis and can be flipped only in the opposite direction. The Raman spectra in linear polarizations are similar, but co-polarized (blue curve) and cross-polarized (red curve) spectra consist of the peaks at even and odd frequencies only, respectively, see Eqs. (53). In the same time, the Faraday rotation noise spectrum (black curve) is symmetric and contains the odd peaks only, as it follows from Eq. (54).

In the limit of zero temperature, the expressions for the spectra are particularly simple even beyond the adiabatic approximation. From the spin correlation function (46) and Eqs. (B8) we find that

$$
\langle \mathcal{J}(0) \mathcal{J}(\tau) \rangle = \langle \mathcal{J}^2(0) \rangle e^{i \Omega_L \tau - |\tau|/\tau_s},
$$

and

$$
\langle \mathcal{J}^2(0) \rangle = N s \frac{\omega_{ex}^2}{\Omega_L^2} \left[ 1 - \cos(\Omega_L k/\gamma) \right],
$$

where we took into account that $\tau_s \gamma \gg 1$. Substitution of these expressions in the polarization correlation function (B7) yields the areas of the peaks in the form [18, 20, 21]

$$
A_n^\pm = \frac{1}{2\tau_0^\pm} \int_0^\infty e^{-t/\tau_0} \frac{\Delta I_x^\pm(t)}{n!} e^{-\Delta I_x(t)} dt.
$$

Here we introduced the notations $t = k/\gamma$, $\tau_0 = 1/(2\gamma)$ and [34]

$$
\Delta I_x(t) = \int \omega_{ex}^2 \Omega_L \left[ 1 - \cos(\Omega_L t) \right]
$$

with $I = Ns$ and $\Omega_{tot} = \sqrt{\omega_{ex}^2 + \Omega_L^2}$. Physically, $\Delta I_x(t)$ is the change of $I_x$ during the spin precession in the sum of the exchange and external magnetic fields for the time $t$. The integrand in Eq. (61) has a form of the probability of the change of $I_x$ by $n$ in the Poisson distribution. The integration describes the average of this probability during the exponential exciton decay described by $e^{-t/\tau_0}$.

Fig. 3 shows the spectra for different temperatures, or equivalently for different magnetic fields. For better visibility we focus on the Raman spectrum $S_{\pm +}(\Omega)$, while the Faraday rotation noise spectrum can be obtained by selecting the odd numbered peaks and symmetrizing them in frequency, see Eq. (54). At high temperature (red curve), the spectrum is symmetric, which...
corresponds to purely thermal spin fluctuations. In the limit \( \omega_{ex} \sqrt{N} \gg \gamma \), the peaks are very broad and strongly overlap. At high frequencies the spectrum is described by

\[
S_{++}(\Omega) = \frac{\pi \gamma}{\omega_{ex}} \sqrt{\frac{3 \tau_s}{2 N s (s+1) |\Omega|}}. 
\]

(63)

The fact that \( S_{++}(\Omega) \) decreases with increase of \( \omega_{ex} \) is caused by the large splitting of the two excitonic resonances in this limit and a small region of values of \( \delta I_z \), which produces sizable Faraday rotation, see Eq. (13).

With decrease of the temperature the spectrum becomes asymmetric, which evidences the increasing role of non-commutativity of spin components. In the limit of zero temperature the spectrum contains the Stokes components only. In this limit \( \mu_+ = 0 \) and \( A_n \) decay very slowly obeying the power law:

\[
A_n^{-} \propto 1/\sqrt{n}. 
\]

(64)

C. Favorable conditions for the measurement of the high order correlators

To successfully apply the resonance shift spin noise spectroscopy the exchange interaction should be quite strong. Indeed, in the opposite limit of weak interaction, \( \mu_+ \ll 1 \), the area of the \( n \)-th peak is given by Eq. (56) and is proportional to \( \omega_{ex}^{2n} \). Therefore, the exchange interaction should be strong, which is easily realized in semimagnetic semiconductors and many other systems, see Sec. VI.

Experimentally it is easier to measure the Faraday rotation noise spectra in the sub-GHz frequency range, which corresponds to the weak magnetic fields \( B \lesssim 40 \) mT. In this case the average spin polarization

\[
\langle m(0)m(\tau) \rangle = \frac{5 N \omega_{ex}^2}{4 \gamma^2} e^{i \Omega_L \tau} e^{-|\tau|/\tau_s}. 
\]

(65)

The areas of the peaks decay slowly in this limit as described by Eq. (64). This limit corresponds to the dominance of the quantum spin fluctuations over the classical ones, and was not reached nor approached yet. To measure the Faraday rotation noise in the high frequency range one has to use special techniques, such as pulse trains [35] or heterodyne detection [36]. Nevertheless, we believe that this experimental challenge will be undertaken in the nearest future.
V. NON-GAUSSIAN SPIN NOISE

In the previous sections we described the Faraday rotation noise spectra, and demonstrated, that they give access to the high order quantum spin correlation functions. However, under the assumption of many independent Mn$^{2+}$ spins in the exciton localization volume, the high order spin correlation functions all can be reduced to the second order correlator. So it is interesting to go beyond this approximation and to study the non-Gaussian spin noise.

Generally, the noise spectrum is defined by Eq. (19), where the Faraday rotation and the ellipticity angles are related to the exciton polarization by Eq. (18). Using the averaged polarization correlation function (41) we find the normalized Faraday rotation noise spectrum in the form

\[ S_{FR}(\Omega) = \int_{-\infty}^{\infty} \langle p_y(0)p_y(\tau) \rangle_s e^{i\Omega \tau} d\tau, \]

(67)

where the dimensionless polarization is given by Eq. (35b). In the adiabatic approximation, \( \Omega_L \ll \gamma \), using the definition (26) we obtain

\[ p_y(t) = -\int_{0}^{\infty} e^{-ik-k} M(t)dk, \]

(68)

where we introduced the operator

\[ M(t) = \sin[km(t)]. \]

(69)

Then we perform averaging over the detuning, as defined in Eq. (29), and obtain the spectrum

\[ S_{FR}(\Omega) = \int_{-\infty}^{\infty} d\tau e^{i\Omega \tau} \int_{0}^{\infty} dk e^{-2k} \langle M(0)M(\tau) \rangle_s. \]

(70)

For non-Gaussian spin noise, the cumulants of \( m(0) \) and \( m(t) \) allow one to calculate this correlation function similarly to Sec. IIIA.

For example, in the presence of the resident charge carriers, Mn$^{2+}$ spins are coupled with the carrier-mediated exchange RKKY interaction, which may eventually lead to the transition into the ferromagnetic phase [37]. For the Mn$^{2+}$ concentration approaching the paramagnetic-ferromagnetic transition, their spins are no longer independent, and the spin noise in non-Gaussian. The spin fluctuations in this case can be described theoretically using the Landau theory [38, 39], effective polaron Hamiltonian [40, 41], dynamical mean field theory [42, 43], or using more sophisticated approaches [44, 45]. In the vicinity of the phase transition the effective Larmor frequency decreases [46] and role of higher order cumulants increases [47].

However, in view of the application of the resonance shift spin noise spectroscopy to other systems we consider another situation. Namely, let us study the Faraday rotation noise induced by a single spin \( I \) \((N = 1)\) coupled to the optical resonance. In this case all the cumulants are equally important, see Eq. (B5), so the spin noise is strongly non-Gaussian. This limit can be realized, e.g., for deep impurities or atomic systems, see the next section.

For a single spin it is easier to calculate the Faraday rotation noise spectrum directly using the spin density matrix formalism, than using the cumulant expansion. We find the operator \( M(t) \) from the equation of motion

\[ \frac{dM(\tau)}{d\tau} = \frac{i}{\hbar} [H_0, M(\tau)] + \mathcal{L} \{ M(\tau) \}, \]

(71)

where \( H_0 \) is defined in Eq. (7) and \( \mathcal{L} \) is the Lindblad operator, describing the spin relaxation. Provided the transverse spin relaxation time \( \tau_s \) is much shorter than the longitudinal one \( (T_1) \), we write the Lindblad operator in the form

\[ \mathcal{L} \{ M(\tau) \} = \frac{1}{\tau_s} [2I_x M(\tau)I_x - I^2_x M(\tau) - M(\tau)I^2_x]. \]

(72)

The kinetic equation has a trivial initial condition \( M(0) = \sin(km) \), where \( m \) is the Schrödinger operator defined in Eq. (27). Finally, the correlation function in Eq. (70) should be calculated using the steady state density matrix

\[ \rho = e^{-H_0/(k_BT)} / Tr \left( e^{-H_0/(k_BT)} \right). \]

(73)

As an example let us consider \( I = 1/2 \). In this case

\[ \sin(km) = 2\sin \left( \frac{k\omega_{ex}}{2\gamma} \right) I_z. \]

(74)

Then the solution of Eq. (71) simply reads

\[ M(\tau) = 2\sin \left( \frac{k\omega_{ex}}{2\gamma} \right) [I_z \cos(\Omega_L \tau) + I_y \sin(\Omega_L \tau)] e^{-\gamma/\tau_s}. \]

(75)

For any temperature the correlation function is the same:

\[ \langle M(0)M(\tau) \rangle_s = \sin^2 \left( \frac{k\omega_{ex}}{2\gamma} \right) \cos(\Omega_L \tau) e^{-|\tau|/\tau_s}. \]

(76)

Substituting this function in Eq. (70) we find the non-Gaussian Faraday rotation noise spectrum for \( I = 1/2 \):

\[ S_{FR}(\Omega) = \frac{1}{8} \frac{\omega_{ex}^2}{\omega_{ex}^2 + 4\gamma^2} \left[ \mathcal{P}_1(\Omega) + \mathcal{P}_1(-\Omega) \right]. \]

(77)

This spectrum is shown by the blue curve in the Fig. 4. Note, that its shape formally coincides with the spectrum of spin fluctuations, which is usually measured by the Pauli-blocking spin noise spectroscopy.
Generally, $\sin(km)$ can be presented as a linear combination of the operators $I^n_k$ with odd $n \leq 2I$. As a result, the high order spin correlators can be reduced to a few lower orders, and the spectrum consists of a finite number of peaks. The maximum peaks’ number is $n_{\text{max}} = 2[I - 1/2] + 1$, where square brackets denote the integer part. Similarly, in the multispin flip Raman spectra in circular polarization the maximum peaks’ number is $2I$, which corresponds to the fact, that a single spin can not be flipped more than 2$I$ times in one direction.

The Faraday rotation noise spectrum for a single spin $I = 5/2$ (in the limit $T = 0$) is shown in the inset in Fig 4 by a magenta curve. One can see, that the maximum peaks’ number is 5, and the peaks are much broader, than for the Gaussian spin noise. This indicates, that the higher order spin correlators generally contain more information than the common second order one.

VI. DISCUSSION AND CONCLUSION

To detect the higher order spin correlators, the ratio between the exchange broadening of the exciton resonance $\sqrt{N}\omega_{ee}$ should be comparable to or larger than the homogeneous linewidth $\gamma$, as shown in Sec. IV C. This condition is easily satisﬁed in Mn-doped QWs [18] and QDs [19], where up to 15 peaks in the Raman spin flip spectra are visible. For these structures $\sqrt{N}\omega_{ee} \sim 2$ meV and $\gamma \sim 1$ meV.

For Mn-doped nanosystems, the number of the probed spins is typically very large $N \gtrsim 100$, and the total spin noise is almost Gaussian. However with increase of the Mn$^{2+}$ concentration a limited number of closely located pairs of magnetic atoms appears. The strength of the exchange interaction in a pair can be of the order of 0.5 meV [48–50], and the ground state of the pair is the singlet spin state. The difference between the interaction constants with the heavy hole in the localized exciton for the two spins in a pair leads to the mixing between singlet and triplet states. We expect, that it will manifest itself as another comb of peaks with the frequencies a bit larger than $n\Omega_L$ in Faraday rotation noise spectrum. Due to the small number of pairs their contribution is non-Gaussian, and therefore contains detailed information about the spin dynamics of the pair of strongly coupled spins.

Importantly, the resonance shift quantum spin noise spectroscopy can be applied to a very broad class of spin systems. For example, it can be applied to measure the nuclear spin fluctuations in QDs. In this case the main requirement for the detection of high order spin correlators is the sizable hyperfine interaction strength as compared with the inverse lifetime of the excited state. For example, in GaAs-based QDs the hyperfine interaction constant for electrons is $A \approx 100$ $\mu$eV [17, 51], so for small QDs with $N \sim 10^4$ one has $\sqrt{N}\omega_{ee} \sim A/\sqrt{N} \sim 1$ $\mu$eV, which is the typical exciton homogeneous linewidth [52]. Thus we expect, that the higher order nuclear spin correlators can be measured for small QDs as well as for the small colloidal nanocrystals.

Resonance shift spin noise spectroscopy is particularly useful, when the number of probed spins is small, because in this case the high order spin correlators can not be reduced to the lower orders. To measure these correlation functions, the spin-related (e.g. hyperfine) structure of individual optical transitions should be visible. There are many examples of such systems: For NV$^-$ centers in diamond the hyperfine interaction constant with the nearest C$^{13}$ atom can reach 0.1 $\mu$eV [53], which is approximately two times larger, than the homogeneous linewidth at liquid helium temperatures [54]. For rare earth ions, $A$ can reach 10 $\mu$eV, while the homogeneous linewidth is a few times smaller [55]. In the past few years the van der Waals heterostructures are under intense investigation. For localized spatially indirect excitons, the hyperfine interaction induced spin relaxation time is predicted to be $T_2^* \sim \hbar/(\sqrt{N}\omega_{ee}) \sim 1$ ns [56, 57], which is an order of magnitude shorter, than the exciton lifetime $1/\gamma = 10$ ns [58], so the nuclear related broadening of the optical transition exceeds its linewidth by an order of magnitude thanks to the small exciton Bohr radius. The similar situation is also realized for the lead halide perovskites where $T_2^*$ is comparable with $1/\gamma$ [59]. So these systems are prominent for the resonance shift nuclear spin noise spectroscopy. Apart from the solid state physics, the hyperfine structure of optical transitions is quite routinely observed for atoms, such as K, Na, Rb, Cs; and for simple molecules, such as I$_2$ [60]. Therefore these systems are also promising for the resonance shift spin noise spectroscopy.

In conclusion, we have developed a theory of a class of optical phenomena that occur in optically transparent solids with localized spins (e.g. Mn$^{2+}$ spins in diluted magnetic semiconductors), forming a basis for a set of experimental methods, which can be generically called resonance shift spin noise spectroscopy. The distinctive feature of these phenomena is that the spins do not directly participate in the probed optical transitions (e.g. excitonic ones), but they shift such transitions via the spin-spin interactions. To demonstrate the universality and power of this approach, we obtained the expressions for multispin flip Raman spectra in diluted-magnetic quantum wells and calculated the Faraday rotation noise spectra. We predict multiple overtones of the Larmor frequency in the spectra, which reflect the contributions of the high order correlation functions of the spin fluctuations. Our predictions open a way for the experimental investigation of high order spin noise, including quantum noise. Our approach is directly extendable to a wide range of solid-state and atomic systems.

Appendix A: Calculation of the polarization

We start from the general form of the Hamiltonian (1). Its Hilbert space is a direct product of the states of the spin system and the excitonic states including exciton vacuum state. For heavy hole excitons there are four states, which can be labeled by the electron spin projection $S_z^e = \pm 1/2$ and the hole spin $S_z^h = \pm 3/2$. The excitonic states can be denoted as $|k\rangle$, where $k = 1, 2, \ldots$. In the first order in the incident field amplitude, one can consider a single exciton states only, so the exciton Hamiltonian has the form

$$H_{exc} = \sum_k \mathcal{H}_{exc}^{k,k^\prime} c_k^\dagger c_k,$$

where $c_k$ ($c_k^\dagger$) are the annihilation (creation) operators for the states $|k\rangle$. This Hamiltonian describes the fine structure of the excitonic levels and exciton interaction with the external magnetic field.

The coherent exciton generation is described by Eq. (3), where

$$P(t) = \sum_k d_k c_k$$

with $d_k$ being the dipole moments of the excitonic states. In the particular model, which is used in the derivation of Eq. (11), there are two excitonic states with the dipole moments $d_\pm = d(-e_x \mp ie_y)/\sqrt{2}$, where $e_x$ are the unit vectors along the corresponding axes.

The Hamiltonian $H_0$ describes the magnetic spin system only and does not contain operators $c_k$ and $c_k^\dagger$. Moreover, the Hamiltonian of the spin-exciton exchange interaction has the form

$$H_{int} = \sum_{k,k^\prime,d} I_{kk^\prime}^{d} c_k^\dagger c_k^\dagger c_{k^\prime}.$$  

Note, that this Hamiltonian contains off diagonal terms (with $k \neq k^\prime$) and coincides with Eq. (2). The operator of the system evolution is

$$U = \mathcal{T} \exp \left[ -\frac{i}{\hbar} \int_0^t \mathcal{H}(t') dt' \right],$$

and the Heisenberg polarization operator is

$$P^{(0)}(t) = U^\dagger P U.$$  

We are interested in the contribution $P(t)$ to $P^{(0)}(t)$ only, which is linear in the amplitude of the probe light $E$. This operator acts only in the Hilbert space of the exciton vacuum state, so it is given by

$$P(t) = e^{\frac{i}{\hbar} \int_0^t (H_0 + H_{exc} + H_{int}) \tau} \times \frac{i}{\hbar} \left( P^\dagger E \right) e^{-\frac{i}{\hbar} \int_0^t (H_0(t - \tau)) d\tau}. $$

Since the spin Hamiltonian $H_0$ commutes with $P$, this expression can be written as

$$P(t) = \frac{i}{\hbar} \int_0^t \Phi(t,\tau) d\tau \left( P^\dagger E \right),$$

where

$$\Phi(t,\tau) = e^{\frac{i}{\hbar} \int_0^\tau (H_0 + H_{exc} + H_{int}) \tau} e^{-\frac{i}{\hbar} \int_0^{t-\tau} H_0(t-\tau')} d\tau'.$$

To simplify this expression we note that

$$\frac{\partial \Phi(t,\tau)}{\partial \tau} = -\frac{i}{\hbar} \Phi(t,\tau) \left[ H_{exc} + \tilde{H}_{int}(t-\tau) \right]$$

with $\tilde{H}_{int}(t)$ given by Eq. (5). One can readily see, that $\Phi(t,0) = 1$, so the solution of this equation is

$$\Phi(t,\tau) = \mathcal{T} \exp \left\{ \frac{i}{\hbar} \int_0^\tau \left[ H_{exc} + \tilde{H}_{int}(t-\tau') \right] d\tau' \right\}.$$

Substituting this expression in Eq. (A7) we see, that

$$P(t) = \mathcal{P} \psi,$$

where

$$\psi = \frac{i}{\hbar} \int_0^t \mathcal{T} \exp \left\{ \frac{i}{\hbar} \int_0^\tau \left[ H_{exc} + \tilde{H}_{int}(t-\tau') \right] d\tau' \right\} \times \left( P^\dagger E \right),$$

in agreement with Eq. (6). One can readily check, that it satisfies Eq. (4) indeed.

Appendix B: Cumulant expansion

The generating function for the cumulants of $J(0)$ and $\mathcal{J}(\tau)$ can be taken in the following form:

$$\mathcal{K} = \ln \left\langle e^{\alpha J(0) - \beta \mathcal{J}(\tau)} \right\rangle. $$

Its Tailor series defines the cumulants $K\left(J(0), \mathcal{J}^{(n-1)}(\tau)\right)$ as

$$K = \sum_{n=1}^{\infty} \sum_{l=0}^{n} \binom{n}{l} \alpha^l (-\beta)^{n-l} K \left( J(0), \mathcal{J}^{(n-l)}(\tau) \right).$$

(B2)
Comparing this expression with the correlator in Eq. (29) we find
\[
\left\langle \mathcal{T} e^{i\mathcal{J}(0)} \mathcal{T} e^{-i\mathcal{J}(\tau)} \right\rangle = \exp \left\{ \sum_{n=1}^{\infty} \frac{2n}{(2n-1)!} (2n-1) \right\}
\kappa \left( \mathcal{J}^{(0)}, \mathcal{J}^{(2n-1)}(\tau) \right),
\]
where we took into account that the cumulants of the odd orders vanish in the absence of the spin polarization along the z axis \((\langle m(t) \rangle = 0)\). The cumulants of the operators should be calculated using the normal time ordering for \(\mathcal{J}(\tau)\), reverse time ordering for \(\mathcal{J}(0)\) and putting \(\mathcal{J}(0)\) always to the left of \(\mathcal{J}(\tau)\).

To simplify the following, we assume, that the \(M_n^{2+}\) spins, \(I_i\) in Eq. (8), are independent. In this case \(\mathcal{J}(t)\), as defined in Eq. (26) also consists of \(N\) independent contributions \(\mathcal{J}_i(t) \sim 1/N\). Then a cumulant of the sum of independent variables takes the form [30]
\[
\kappa \left( \mathcal{J}^{(0)}, \mathcal{J}^{(2n-1)}(\tau) \right) = \sum_{i=1}^{N} \kappa \left( \mathcal{J}_i^{(0)}, \mathcal{J}_i^{(2n-1)}(\tau) \right).
\]

From this relation one can see the scaling law for the cumulants
\[
\kappa \left( \mathcal{J}^{(0)}, \mathcal{J}^{(2n-1)}(\tau) \right) \propto 1/N^{2n-1}.
\]
The larger is \(N\) the less important are the cumulants of the high orders.

In the limit of many independent \(M_n^{2+}\) spins, \(N \gg 1\), one can neglect all the cumulants except for \(n = 1\) (the second order one). This corresponds to the normal or Gaussian spin noise. In this case Eq. (B3) reduces to
\[
\left\langle \mathcal{T} e^{i\mathcal{J}(0)} \mathcal{T} e^{-i\mathcal{J}(\tau)} \right\rangle = \exp \left( \langle \mathcal{J}(0) \mathcal{J}(\tau) \rangle - \langle \mathcal{J}^2(0) \rangle \right),
\]
and from Eq. (29) we obtain
\[
\langle p_+^*(0) p_+^{(\tau)} \rangle = \int_0^{\infty} e^{-2k+\langle \mathcal{J}(0) \mathcal{J}(\tau) \rangle - \langle \mathcal{J}^2(0) \rangle} dk.
\]

The second order correlator of \(\mathcal{J}(t)\) can be presented as a double integral using its definition (26). The correlation function \(\langle m(t_1)m(t_2)\rangle\) depends on \(t_1 - t_2\) only, so the double integral can be reduced to a single integral as follows:
\[
\langle \mathcal{J}(0) \mathcal{J}(\tau) \rangle = \int_{-\infty}^{k} (k - k') \langle m(0)m(\tau + k'/\gamma) \rangle dk',
\]
and
\[
\langle \mathcal{J}^2(0) \rangle_s = 2 \int_{0}^{k} (k - k') \langle m(0)m(k'/\gamma) \rangle_s dk'.
\]

Substitution of these expressions in Eq. (B7) yields the polarization correlation function, which defines the Raman spin flip spectrum, see Eq. (48).

**Appendix C: Areas of the peaks**

In the realistic limit \(\tau_s \gamma \gg 1\) using Eq. (45) we obtain from Eq. (B8)
\[
\langle \mathcal{J}(0) \mathcal{J}(\tau) \rangle = \langle \mathcal{J}_+ e^{-i\Omega_L \tau} + \mathcal{J}_- e^{i\Omega_L \tau} \rangle e^{-|\tau|/\tau_s}
\]
and
\[
\langle \mathcal{J}^2(0) \rangle_s = \langle \mathcal{J}^2(0) \rangle
\]
with
\[
\mathcal{J}_\pm = \frac{\omega_{ex}}{\Omega_L^2} \left( \langle I_z^2 \rangle + \frac{\langle I_z \rangle^2}{2} \right) \left[ 1 - \cos \left( \frac{\Omega_L k}{\gamma} \right) \right].
\]

Substituting these expressions in Eq. (B7) and decomposing the exponent into series like in Eq. (59) we find
\[
\langle p_+^*(0) p_+^{(\tau)} \rangle = \sum_{n=0}^{\infty} \sum_{l=0}^{n} \frac{\epsilon^{i(2n-1)\Omega_L \tau - n|\tau|/\tau_s}}{l!(n+l)!} \int_0^{\infty} \mathcal{J}_+^l \mathcal{J}_-^{n-l} e^{-2k\mathcal{J}_+ \mathcal{J}_- - 2 \mathcal{J} \mathcal{J}^{(2n-1)}} dk.
\]
where we assume \( \text{sign}(0) \equiv 1 \) to be specific. Finally, the Fourier transform of this expression [see Eq. (48)] yields

\[
S_{++}(\Omega) = \sum_{n \neq 0} \int_{0}^{\infty} e^{-2k} e^{-k^2(\mu_+ + \mu_-)} k^{2(n+2)} \frac{\mu_{n}^{l} e^{-k^2} \mu_{n}^{l+1}}{l!(n+1)!} \mathcal{P}_{n,n+2}(\Omega) dk, \tag{C6}
\]

where we omitted the primes for the brevity, neglected the terms with \( n = 0 \), and introduced the Lorentzian functions

\[
\mathcal{P}_{n,n'}(\Omega) = \frac{2\tau_s/n'}{1 + [(\Omega - n\Omega_L)\tau_s/n']^2}, \tag{C7}
\]

which describe the peaks at the frequencies \( \pm n\Omega_L \) with the widths \( n'/\tau_s \).

[34] The integral in Eq. (61) converges at $\Delta \Omega(\omega) \lesssim 1$. Since $\omega > 1$ one has either $\omega \ll \Omega$ or $\omega \ll \Omega_L$, so one can replace $\Omega_{tot}$ with $\Omega$ and find $\Delta \Omega_L(t) = \langle \hat{J}^2(t) \rangle$.
