ABSTRACT. The efficiency of spermatogonial stem cell (SSC) isolation and culture from pubertal donors is currently poor primarily, because of contamination with other testicular cells. This study aimed to purify SSC-like cells using different extracellular matrixes and a discontinuous gradient density. In experiment 1, testes (n=6) were analyzed for histology and SSC-related protein expressions (laminin, SSEA-4, DDX-4 and GFRα-1). After enzymatic digestion, the cell suspension was plated onto either a laminin- or gelatin-coated dish. The number of SSC-like cells was determined at 15, 30 and 60 min of culture (experiment 2). Experiment 3 was performed to test whether or not the additional step of Percoll gradient density centrifugation could really improve purification of SSC-like cells. Testicular histology revealed complete spermatogenesis with laminin expression essentially at the basal lamina of the seminiferous tubules. SSEA-4 and GFRα-1 co-localized with DDX-4 in the spermatogonia. The relative percentage of SSC-like cells, as determined by cells expressing SSEA-4 (59.42 ± 2.18%) and GFRα-1 (42.70 ± 1.28%), revealed that the highest SSC-like cell purity was obtained with the 15-min laminin-coated dish compared with other incubation times and gelatin treatment (P<0.05). Percoll treatment prior to laminin selection (15 min) significantly improved SSC-like cell recovery (91.33 ± 0.14%, P<0.001) and purity (83.82 ± 0.05% for SSEA-4 and 64.39 ± 1.51% for GFRα-1, P<0.05). These attached cells demonstrated a typical SSC-like cell morphology and also expressed POU5F1, RET and ZBTB16 mRNA. In conclusion, double enrichment with Percoll gradient density centrifugation and laminin plating highly enriched the SSC-like cells population.

KEYWORDS: extracellular matrix, feline, purity, spermatogonial stem cell

doi: 10.1292/jvms.15-0207; J. Vet. Med. Sci. 77(11): 1347–1353, 2015

Spermatogenesis is a complex process of male germ cell production, in which diploid spermatogonia or spermatogonial stem cells (SSCs) transform and differentiate into haploid spermatoozoa within seminiferous tubules. This process is regulated by intra- and extra-testicular factors and continues throughout the pubertal period in men and animals. Although the SSCs hold a great promise for the treatment of infertility problems in men due, for example, to premature loss of male germ cells following cytotoxic chemotherapy, these SSCs can also be used for propagation and preservation of the genetic profiles of valuable male animals, such as endangered species [20]. In addition, SSCs have recently been reported to be capable of differentiation into 3 germ layers of embryos including cardiomyocytes, smooth muscle cells, neural cells, endothelial cells, hepatocytes and renal tubular cells [4, 6, 7, 10, 21]. The SSCs have therefore become an emerging model for regenerative medicine. SSCs are a subpopulation of spermatogonia type A that settle on the basal lamina of the seminiferous tubule. The number of SSCs, however, has been estimated to be only 0.03% of the total testicular cells in the adult rat testis[37]. Thus, purification of SSCs from the digested pubertal testis has become an important step for isolation of SSCs, since this technique eliminates the somatic testicular cells that interfere with the proliferation of SSCs in vitro [23, 37]. Several studies in the mouse, rat and bull have reported efficient techniques for SSC enrichment including plating with different coating substances, discontinuous Percoll gradient density centrifugation and fluorescence-activated/magnetic-activated cell sorting (FACs/MACs) [8, 12, 15, 26, 34]. The SSCs surrounded by Sertoli cells are adhered to the basal lamina of seminiferous tubules by various extracellular matrixes (ECMs) [35]. These ECMs are important for attachment of the testicular cells to the basal lamina of seminiferous tubules and also for the formation of the SSC niche [34]. Various types of ECMs have been used to purify the SSC population, such as laminin, fibronectin, collagen type I and IV and gelatin [18, 19, 28]. Of substrates used to coat the culture dish, gelatin has generally been used, because it is cost-effective for optimization of cell attachment in various cell types, such as fibroblasts. The gelatin plays a role in denaturing collagen, as connective tissue, and also interacts with laminin and fibronectin. Although the efficiency of laminin in selecting SSCs in the domestic cat has yet to be examined, the laminin-coated plate has been demonstrated to improve the purifying efficacy of SSC isolation by 3.3-, 5- to 7- and 8.5-folds in bull, mouse and rat SSCs, respectively [13, 31, 35]. This high efficiency of laminin for SSC selection has been postulated to be associated with its receptors on the SSCs [34]. Although the attachment of SSCs to laminin involves integrin proteins, a laminin receptor [15],

\(\alpha_\text{v}\)-integrin, was the only specific surface marker of SSCs in the mouse [34]. In addition to plating selection, Percoll\textsuperscript{TM} purification, which involves nontoxic gradient density centrifugation, has been performed to recover the specific populations of testicular cells via different gradient density and centrifugation. This technique recovered approximately 80%, 72% and 96% of rat, buffalo and pig SSCs, respectively [9, 32, 37]. Moreover, the viability of SSCs recovered from Percoll\textsuperscript{TM} was also improved [37].

The objective of this study was to examine the effects of types of ECM substrates and Percoll\textsuperscript{TM} gradient density on the enrichment of SSC-like cells in pubertal domestic cats.

**MATERIALS AND METHODS**

**Experimental designs**

**Experiment 1: The localization and immunolabeling of SSCs in pubertal cat testes**

Cat testes (n=6) were collected from pubertal domestic cats. The testes were fixed and sectioned for routine histology, immunohistochemistry (laminin) and immunofluorescence for SSC markers. Immunofluorescence was performed to demonstrate the co-expressions of SSEA-4/DDX-4 and GFRα-1/DDX-4 as SSC makers. The localization and expression pattern for each marker was descriptively analyzed.

**Experiment 2: The enrichment efficiency of SSCs using different types of ECMs**

The testes (n=6) were dissociated into single cells by a modified 2-step enzymatic digestion [36]. The digested testicular cells (0.5 x 10\textsuperscript{6} cell/cm\textsuperscript{2}) were plated dishes coated with laminin (20 µg/ml) and gelatin (0.1% (w/v)) coated dishes for 15, 30 and 60 min. The attached testicular cells were fixed and examined for SSEA-4 and GFRα-1 expression using fluorescence microscopy. The percentages of SSEA-4\textsuperscript{+} and GFRα-1\textsuperscript{+} from different types of ECMs among the different time points were analyzed.

**Experiment 3: Double enrichment of the SSC population with Percoll\textsuperscript{TM} and laminin plating**

Suspension of dissociated testicular cells (n=6, 2 x 10\textsuperscript{6} cell/ml) was first layered onto a discontinuous Percoll\textsuperscript{TM} gradient as previously described [26] with some modifications. The Percoll\textsuperscript{TM} layers containing SSC-like cells were subsequently plated onto laminin-coated dishes for 15 min. The SSEA-4\textsuperscript{+} and GFRα-1\textsuperscript{+} cells were determined. In addition, the attached cells were collected for a study of SSC-related gene expression (POUSF1, RET and ZBTB16) and a differentiation marker (KIT).

**Animals and sample preparation:** Tomcats (aged between 1–2 years old) were used in this study. Cat testes were consentingly collected following routine castration at the Veterinary Public Health Division of the Bangkok Metropolitan Administration, Bangkok, Thailand. The testes were transported to the laboratory in saline solution supplemented with antibiotics (100 IU/ml penicillin and 100 µg/ml streptomycin) at room temperature. They were dissected from extraneous testicular tissues prior to use. The testes were divided for fixation with 4% (w/v) paraformaldehyde in phosphate-buffered saline (PBS) (Exp. 1) and for dissociation with enzymatic digestion (Exp. 2 and 3).

**Histology, immunohistochemistry and immunofluorescence:** For histology and immunohistochemistry, testicular tissue was fixed with 4% (w/v) paraformaldehyde (BDH Prolabo, VWR, Poole, U.K.) in PBS at 4ºC (overnight). The fixed testes were embedded in paraffin and cut at a thickness of 4 µm. Hematoxylin and eosin staining was used to study the structures of the testis.

To detect the expression of laminin, a 3-step indirect immunoperoxidase immunohistochemistry (IHC) was performed with a Leica Microsystems BOND-MAX System (Leica Microsystems, Bannockburn, IL, U.S.A.). Briefly, the epitopes of the antigen were retrieved with Bond Epitope Retrieval Solution 2 (Leica Microsystems) for 20 min at 100ºC. The slides were incubated with an anti-mouse monoclonal laminin antibody diluted 1:100 (Novocasta\textsuperscript{TM}, Leica Microsystems) at 25ºC for 45 min. Post Primary Polymer (Leica Microsystems) was applied for 9 min and followed with Polymer Poly-HRP IgG (Leica Microsystems) for 7 min. Mouse IgG (PP54, Millipore, Darmstadt, Germany) was used instead of the primary antibody for the negative control.

For immunofluorescence (IF) on paraffin-embedded sections, the epitope was unmasked by microwave treatment at 900 watts for 15 min in citric acid buffer (BDH Prolabo; pH=6.0) supplemented with 0.03% (v/v) Triton X-100. Non-specific staining was blocked using 3% (w/v) bovine serum albumin (BSA) in PBS. The sections were firstly incubated at 4ºC overnight with either mouse monoclonal SSEA-4 (1:200, Abcam, Cambridge MA, U.S.A.) or mouse monoclonal GFRα-1 (1:200, sc-10716, Santa Cruz Biotechnology, Dallas, TX, U.S.A.). They were further incubated with the corresponding secondary antibody (goat anti-mouse IgG TRITC, 1:200). Subsequently, the sections were co-stained with the primary antibody (rabbit polyclonal DDX-4, 1:100, Abcam) and followed by goat anti-rabbit IgG FITC (1:100, Abcam). For the negative control, the staining procedures were identically performed as described above except that the primary antibodies were replaced with mouse IgG (PP54, Millipore, Darmstadt, Germany) or rabbit IgG (PP64, Millipore). The co-expression of SSEA-4/DDX-4 and GFRα-1/DDX-4 markers was visualized with a fluorescence microscope (BX5, Olympus, Tokyo, Japan).

The photomicrographs obtained from histology, IHC and IF were recorded using the cellSens software (Olympus) and Adobe Photoshop CS6 Version 13.0.1 (Adobe Systems, San Jose, CA, U.S.A.).

For digested testicular cells, the cell suspension or attached cells were fixed with 4% (w/v) paraformaldehyde in PBS for 24 hr at 4ºC and then labeled with primary and secondary antibodies as mentioned above (SSEA-4/TRITC, GFRα-1/TRITC). The fixed cells were also blocked with 3% (w/v) BSA in PBS to reduce nonspecific background stain-
Viability test and enrichment of SSC-like cells: Testes were enzymatically dissociated to obtain single testicular cells as previously described [36]. The testicular cells were examined for viability in terms of esterase enzyme activity (calcein AM staining) and plasma membrane integrity (ethidium homodimer-1, Molecular Probes, Life Technologies, Carlsbad, CA, U.S.A.). For differential plating selection, the culture dishes were first coated with either 20 µg/ml laminin or 0.1% (w/v) gelatin at 37°C for 4 hr before cell plating. The dissociated testicular cells (0.5 x 10^6 cells/cm^2) were plated onto laminin- or gelatin-coated dishes. The cells were further incubated for 15, 30 and 60 min, and then, the samples were fixed and collected for immunostaining. Culture was performed at 37°C in a moisture incubator with 5% CO_2 in air.

Percoll™ gradient density centrifugation was performed by layering the cell suspension (2 x 10^6 cells/ml) onto 30%, 45%, 60% and 90% (v/v) isotonic Percoll™ solution, respectively. The cells were then centrifuged at 800 x g for 30 min at 25°C. The thin layers of cell suspension at interfaces between the two concentrations of Percoll™ were gently collected.

RT-PCR for SSC-related gene expression: The attached testicular cells were collected and extracted to obtain total RNA using an Absolutely RNA Nanoprep Kit (Stratagene™, Agilent Technologies, Santa Clara, CA, U.S.A.). The total RNA (2 ng/µl) was reversely transcribed using the Super-Script™ III First-Strand Synthesis System for RT-PCR (Invitrogen, Carlsbad CA, U.S.A.) for cDNA synthesis (RT+). Removal of SuperScript™ III reverse transcriptase was performed for the negative control (RT-). PCR was performed with RT+ and RT- cDNA using GoTag® Green Master Mix (Promega, Fitchburg, WI, U.S.A.). In brief, the PCR conditions consisted of denaturation (2 min at 95°C); 30 cycles of 30 sec at 95°C, 30 sec at the annealing temperature for each primer and 30 sec at 72°C; and final extension (2 min at 72°C). The PCR products were electrophoresed in 1% (w/v) agarose gel (Bio-Rad, Hercules, CA, U.S.A.) supplemented with 5% (v/v) RedSafe™ Nucleic Acid Stain Solution (iNtRON Biotechnology, Gyeonggi-do, South Korea) in TBE buffer. The products were detected by a Gel Documentation system (Syngene, Cambridge, U.K.).

The primers and annealing temperatures used in this study were as follows: POU5F1 (5’-TGAGAGGCAACCTGGAGA-3’ and 5’-AACCACACTCGGACCACATC-3’, 55°C, 112 bp, accession number: EU366914), RET (5’-TGTGCATGTACAGGCTGG-3’ and 5’-CCTGCTCACAGTGAGG-3’).
GT-3', 63°C, 193 bp, accession number: XM_003994195.1), ZBTB16 (5′-GCAAGAAGTTCAGCCTCAAGC-3′ and 5′-GCTTGATCATGGCCGAGTAGTC-3′, 63°C, 119 bp) [36] and KIT (5′-TCCTGCTCCGCGTCCAGACA-3′ and 5′-CTTGCCCTTCCGGTCCGCAG-3′, 60°C, 533 bp) [36]. GAPDH was used as a housekeeping gene [36].

Statistical analysis: The percentages of SSEA-4+ and GFRα-1+ testicular cells and viability were expressed as the mean ± SEM. The data were analyzed with SPSS Statistics Version 20.0.0 (IBM Corporation, Armonk, NY, U.S.A.). The statistical differences between the groups were tested by analysis of variance (ANOVA) followed by the Bonferroni post hoc test. Differences between values with P<0.05 were considered statistically significant.

RESULTS

The localization and immunolabeling of SSCs in pubertal cat testes: Histological examination of pubertal cat testes demonstrated fully differentiation of male germ cells in the seminiferous tubules. Spermatogonia including SSCs resided on the basal lamina of the seminiferous tubule and were surrounded by Sertoli cells. The spermatogonia differentiated into spermatocytes, spermatids and spermatozoa (Fig. 1a). For IHC of laminin, expression of this protein was observed in the spermatogonia present at the basal lamina of the seminiferous tubules. Laminin was also essentially expressed at the extracellular matrixes of the testis, such as the basal lamina of seminiferous tubules and blood vessels (Fig. 1b). The spermatogonia (SSCs) expressed SSEA-4 at the plasma membrane and cytoplasm. These cells co-expressed with DDX-4 (Fig. 1c). However, DDX-4 was also detected in other testicular germ cells, such as spermatocytes and round spermatids. Similar to SSEA-4+, co-expression of GFRα-1 and DDX-4 was clearly observed in the spermatogonia located on the basal lamina (Fig. 1d).

The enrichment efficiency of SSCs using different types of ECMs: After enzymatic isolation, the viability of isolated testicular cells was 66.56 ± 1.43%. The percentages of SSEA-4+ and GFRα-1+ testicular cells attached to different ECMs are shown in Table 1. On the laminin-coated surface, adhered SSC-like cells had a typical SSC-like cell morphology as shown in a previous study. They were round to oval cells (ranged 8–13 µm of size) with an increased nucleus/cytoplasm ratio (Fig. 2b). However, all attached testicular cells were contaminated with mixed populations of other testicular cells, such as Sertoli cells, fibroblasts, spermatids and other testicular cells. The laminin-coated plate technique significantly enriched the SSEA-4+ population of testicular cells when examined at 15 (59.42 ± 2.18%) and 30 min (53.37 ± 1.08%) of incubation. These percentages were significantly higher than the percentage for non-treatment (27.24 ± 1.29%, P<0.001). GFRα-1 testicular cells tended to increase in cell number at 15 (42.70 ± 1.28%) and 30

Fig. 2. Morphology of testicular cells after testicular cell digestion and enrichment. Following a modified 2-step enzymatic digestion, testicular cells contain several stages of spermatogenesis (a). Laminin was successfully used to enrich morphologically undifferentiated spermatogonia (or SSC-like cells (arrow)) (b). The SSC-like cells are round to oval in shape and have a high nucleus/cytoplasm ratio (closed up, b). Percoll gradient density treatment (c and d, at 30% layer, c and 30%/45% interface, respectively), improved cell viability and cell purity. Scale bar=50 µm.
The numbers of SSEA-4 and GFRα-1+ testicular cells examined at 60 min of incubation decreased significantly to 16.77 ± 2.59% and 20.90 ± 1.06%, respectively (P<0.001). The numbers of SSEA-4+ and GFRα-1+ cells attached to gelatin were significantly lower compared with those attached to laminin at all incubation times (Table 1, P<0.001). The attached SSEA-4+ and GFRα-1+ cells on gelatin-coated dishes also decreased significantly from 9.05 ± 1.07% to 5.34 ± 0.22% and 10.97 ± 0.84% to 2.00 ± 0.17% when examined at 15 and 30 min, respectively (P<0.001). The gelatin-bound cells at 60 min of incubation were the highly contaminated with attached fibroblasts.

**Double enrichment of SSCs with Percoll™ and laminin plating:** After discontinuous Percoll™ gradient density centrifugation, the majority of testicular cells were found at 2 Percoll™ densities (at 30% and the interface between 30% and 45% solutions (30%/45%). Spermatozoa, red blood cells and other cell debris were observed at other Percoll™ interfaces. A thin layer of testicular cells at 30% Percoll™ yielded higher cell numbers than that obtained from the 30%/45% interface (91.33 ± 0.14%) was significantly higher than that of the 30% layer (78.40 ± 0.23%) and non-treatment (66.56 ± 1.43%) (P<0.001). Double enrichment with Percoll™ and Laminin (Percoll™+Laminin) significantly improved SSEA-4+ and GFRα-1+ cells when compared with only laminin treatment (P<0.001). This double enrichment also improved cell uniformity. However, some sperm heads were also found in laminin-coated dishes (Fig. 2b). We confirmed that the attached cells derived from double enrichment with Percoll™+Laminin expressed the SSC-related genes (POU5F1, RET and ZBTB16 mRNA) but that the differentiated gene (KIT mRNA) was absent (Fig. 3).

**DISCUSSION**

This study revealed that only small numbers of testicular cells demonstrated morphologic and phenotypic SSC characteristics within pubertal testes of domestic cats. The limited numbers of SSC-like cells have been proposed to attenuate the success of SSC-like cell isolation and culture. The enrichment step has therefore become a critical part for establishment of SSCs in vitro, especially for species in which well-characterized SSCs have yet to be reported. In

phatidyl inositol GFRα-1 surface receptors and its RET tyrosine kinase co-receptors in the cell plasma membrane [2, 13]. This GDNF has been demonstrated to play a central role for in vivo and in vitro activities of SSCs [25, 26]. Our study also demonstrated that laminin, an extracellular matrix, surrounded the spermatogonia and was present at the basal lamina of the seminiferous tubules. Although attachment of SSCs to laminin involves integrin proteins, a laminin receptor [14], α6- and β1-integrins were the only specific marker of SSCs in mouse [34]. In this study, we found that purified SSC-like cells rapidly adhered to laminin-coated surfaces within 15 min of incubation (Table 1). This short incubation maximized the SSC-like cells with minimal contaminating cells, and therefore, it is recommended for SSC isolation, as similarly reported in a previous report in the mouse [35].

In conclusion, we demonstrated that the SSC-like cells of domestic cats expressed SSEA-4 and GFRα-1, which can be used as SSC markers. The SSC-like cells preferentially attached to laminin, but the purity of the cells was time dependent. This technique combined with the discontinuous Percoll™ gradient density centrifugation significantly improved the viability and viability of SSC-like cells from the domestic cats. Double enrichment, in particular, can be applied as a prerequisite tool for in vitro culture of cat SSC-like cells to enrich the SSC-like cell population.

DECLARATION OF INTEREST
