ABSTRACT

Context. General Relativistic effects on the clustering of matter in the universe provide a sensitive probe of cosmology and gravity theories that can be tested with the upcoming generation of galaxy surveys. These will require the availability of accurate model predictions from large linear scales to small non-linear ones.

Aims. Here, we present a suite of large volume high-resolution N-body simulations specifically designed to generate light-cone data for the study of relativistic effects on lensing-matter observables without the use of simplifying approximations. As a case study application of these data, we perform an analysis of the relativistic contributions to the lensing-matter power spectra and cross-power spectra.

Methods. The RayGalGroupSims suite (or in short RayGal) consists of two N-body simulations of $(2625 h^{-1} \text{Mpc})^3$ volume with 4096$^3$ particles of a standard flat $\Lambda$CDM model and a non-standard $w$CDM phantom dark energy model with constant equation of state. Light-cone data from the simulations have been generated using a parallel ray-tracing algorithm that has integrated billion geodesic equations without the use of flat-sky nor the Born approximation.

Results. Catalogues and maps with relativistic weak-lensing which include post-Born effects, magnification bias (MB) and redshift space distortions (RSD) due to gravitational redshift, Doppler, transverse Doppler, Integrated Sachs-Wolfe/Rees-Sciama effects, are publicly released. Using this dataset, we are able to reproduce the linear and quasi-linear predictions from the Class relativistic code for the 10 power spectra and cross-spectra (3x2 points) of the matter density fluctuation field and the gravitational convergence at $z = 0.7$ and $z = 1.8$. We find 1-30% level contribution from both MB and RSD to the matter power spectrum, while the Fingers-of-God effect is visible at lower redshift in the non-linear regime. MB also contributes at the 10%-30% level to the convergence power spectrum leading to a deviation between the shear power-spectrum and the convergence power-spectrum. MB also plays a significant role in the galaxy-galaxy lensing by decreasing the density-convergence spectra by 20%, while coupling non-trivial configurations (such as the one with the convergence at the same or even lower redshift than the density).

Conclusions. The cosmological analysis shows that the relativistic 3x2 points is a powerful cosmological probe. Our unified approach to relativistic effects is an ideal framework for the investigation of gravitational effects in galaxies studies (clustering, weak-lensing) but also in galaxy clusters, groups or voids studies (gravitational redshifts, weak-lensing) or in CMB studies (Integrated Sachs-Wolfe/Rees-Sciama, weak-lensing).

1. Introduction

Observations of the distribution of galaxies in the Universe carry a wealth of cosmological information pertaining to the cosmic matter content, the state of expansion, the amplitude of matter
density fluctuations, the nature of dark energy and dark matter and enable to test General Relativity (GR) on the large cosmic scales. This is because, in addition to the cosmological imprint arising from the dynamical processes that lead to the formation of cosmic structures, observables of the clustering of galaxies also carry the signature of relativistic effects that alter the path of photons propagating between emitting galaxies and the observer.

Relativistic effects modify the apparent distribution of galaxies and leave a distinct imprint on the galaxy/lensing two-point statistics through various processes: the weak-lensing effect (WL), that alters the apparent angular position, size and shape of galaxies in the sky; the redshift-space distortions (RSD) due to proper motion of the emitting galaxies, the local gravitational potentials and the propagation of light-rays through time-varying potentials.

The present as well as the upcoming generation of galaxy surveys such as eBOSS, HSC, DES, KIDS, DESI, LSST, Euclid and SKA will provide a precise mapping of the distribution of galaxies across a wide range of scales with measurements that are sensitive to such effects. These observational programs will increase the number of galaxies with measured redshifts and/or ellipticities by several order of magnitudes, thus enabling the possibility to perform accurate analyses of weak-lensing and clustering data (as well as their cross spectra, the so-called 3x2pts analysis). This will allow to infer strong constraints on the cosmological model parameters, and test alternative models of dark energy and modified gravity theories, provided the availability of accurate theoretical model predictions.

GR effects on the galaxy two-point statistics beyond the RSD signal caused by the peculiar velocity of galaxies have been investigated in the linear regime in numerous works (see e.g. Yoo et al. 2009; Yoo 2010; Bonvin & Durrer 2011; Challinor & Lewis 2011), while extension to the quasi-linear and non-linear regime have been primarily carried out using approximate analytical approaches (Di Dio & Seljak 2019; Taruya et al. 2020; Saga et al. 2020; Di Dio & Beutler 2020; Beutler & Di Dio 2020). Similarly, studies of GR effects on the weak-lensing shear have been investigated under various approximations. As an example, GR corrections up to second order in the gravitational potential of the lensing shear were computed in Bernardeau et al. (2010), while the imprint on the shear power spectrum in the linear regime where evaluated under the Born approximation in Di Dio et al. (2013).

Analytical and numerical studies of the GR contributions to the gravitational potentials of matter density fluctuations have been found to leave a small imprint on the clustering of matter (Chisari & Zaldarriaga 2011; Adamek et al. 2016a). That is why Newtonian N-body simulations are still a valid tool to investigate relativistic kinematics effects (Fidler et al. 2015, 2016), which on the other hand leave observational imprints which can not be neglected (see e.g Ghosh et al. 2018; Breton et al. 2019).

Several General Relativistic N-body codes have been developed to study these effects in the non-linear regime of the clustering of matter. Nevertheless, the use of approximations at different stages of the numerical computation prevents the possibility of inferring cosmological model predictions that are of general validity. For instance, a standard approach to generate lightcone data from high-resolution N-body simulations consists in using the replica method while assuming the Born approximation (Spier et al. 2020). A ray-tracing method based on the calculation of the lensing distortions of a ray-bundle by solving the geodesic equations was presented in Kiledar et al. (2012). However, the ray-tracing algorithm is limited to a fixed grid, thus not enable to exploit the high spatial resolution that can be achieved by N-body codes with Adaptive Mesh Refinement (AMR).

Adamek et al. (2016b) have developed a numerical GR N-body code in the weak-field limit without AMR. Adamek et al. (2019); Lepori et al. (2020) implemented a ray-tracing algorithm similar to that of Reverdy (2014); Breton et al. (2019), which solves the geodesic equations without relying on the Born approximation and that was used to investigate several relativistic effects on the weak-lensing convergence power spectrum (Lepori et al. 2020), the matter power spectrum multipoles (Guandalin et al. 2020) and the cross-correlation power spectrum between the matter density and lensing convergence (Coates et al. 2020).

Here, we describe and publicly release the numerical data generated from the RayGal simulation suite1, a specifically designed set of simulations to study the relativistic effects on the clustering of matter observables. In particular, the light-cone data have been generated using a ray-tracing algorithm which solves the geodesic equations with the gravitational potential evaluated along the different AMR levels of the N-body solver (Reverdy 2014; Breton et al. 2019; Breton & Fleury 2020). Thus, these numerical datasets benefit of a large dynamical range of the simulations with large volume and high-spatial resolution without the need to rely on the Born approximation or other limiting assumptions. In Breton et al. (2019), the light-cone data from the RayGal simulation of a ΛCDM model were used to perform a study of the asymmetry of the halo cross-correlation function due to the relativistic effects.

In this work, we introduce the complete simulation suite, including data from the simulation of a non-standard dark energy model and perform a case study application of the dataset. In particular, we present the evaluation of relativistic effects on the angular matter density power spectrum, lensing convergence power spectrum, and their cross-spectra. We find a good agreement in the linear and quasi-linear regimes with the analytical predictions from the relativistic code Class, while deviations occur in the non-linear regime. Furthermore, we find a non-negligible imprint of RSD and magnification bias (MB) on the harmonic matter power spectrum (1-30%). At low redshift, the damping due to the Fingers-of-God effect is clearly visible. The MB contributes to the lensing convergence power spectrum to 10 ~ 30% level. As the shear power spectrum is largely insensitive to the magnification bias, this results in important differences with respect to the convergence power. MB also decreases the matter overdensity-gravitational convergence spectra (i.e. galaxy-galaxy lensing) by 20%. By coupling the signal between different redshift shells, relativistic effects boost the correlations between lensing/clustering of matter observables. This is the case of the correlation between the matter density field and the convergence evaluated at the same redshift, as well as that with the convergence measured at a smaller redshift than the density field. The cosmological evolution shows that the relativistic contributions to the 3x2pts statistics make it promising probe of dark energy and modified gravity.

The paper is organized as follows: we describe the RayGal simulations and the associated numerical datasets in Sect. 2; we present a case study of the imprint of relativistic effects on weak-lensing observables using the RayGal data in Sect. 3; finally, we discuss the conclusions in Sect. 4.

2. Methods: simulations, ray-tracing and data

2.1. Cosmological models

The nature of dark energy still remains unknown. In order to test the cosmological dependence of relativistic effects on the clustering of matter observables, we have simulated two different spatially flat cosmological models: a standard ΛCDM model and “phantom” dark energy wCDM model with constant equation of state w = −1.2. The cosmological parameters of these models have been calibrated against the CMB anisotropy power spectra from the WMAP-7 year data (Komatsu et al. 2011), these are summarized in Table 1. The values of Ω_m and σ_8 of the wCDM model have been chosen such as to be within the 1σ confidence region of the WMAP inferred constraints in the Ω_m − σ_8 plane and along the degeneracy line of σ_8 − w contours (see beige filled contours in Fig. 1). Henceforth, this model is statistically indistinguishable at 1σ from ΛCDM best-fit model to the WMAP-7 years data. The simulated models are the same as those selected for the DEUS-Full Universe Runs (Alimi et al. 2012; Rasera et al. 2014; Bouillot et al. 2015). These are also consistent with the constraints from the latest Planck primary CMB analysis within 2σ (TT, TE, EE spectra Planck Collaboration et al. 2020) (see red-yellow filled contours in Fig. 1). Notice that being compatible with Planck data, values of the equation of state varying in the range −1.3 ≤ w ≤ −1 are often considered in the literature (e.g. Alestas et al. 2020 and reference therein), for instance in the context of the “H_0 tension” (Riess et al. 2019). Since these models are hard to discriminate at the homogeneous and linear perturbation level, it is important to find new cosmological probes, for instance in the non-linear regime of cosmic structure formation.

2.2. N-body simulations

The RayGalGroupSims (Ray-tracing Galaxy Group Simulations, or in short RayGal) suite was run at TGCC and CINES French supercomputing centers. It consists of N-body simulations of the ΛCDM and wCDM models respectively, spanning a volume of (2625 h^{-1}Mpc)^3 sampled by 4096^3 dark-matter particles. The optimal compromise between mass resolution (order ~ 2 \times 10^{10} h^{-1}M_\odot depending on the simulated cosmology) and large statistics makes them ideal to investigate the cosmology-dependent distribution and properties of halos from Milky-Way size to galaxy-cluster size (including galaxy-group size halos, which are the main deflectors in weak-lensing studies). The main novelty of these simulations is the relativistic ray-tracing within the gravity light-cones allowing us to build realistic catalogues of dark-matter particles and halos containing relativistic effects.

Initial conditions were generated with a modified version of MPGRAFIC (Prunet et al. 2008). In this code, the density field is generated as a Gaussian random field, while the associated displacement field is computed (in the version we developed) using second-order lagrangian perturbation theory (2LPT). The starting redshift was chosen such as to ensure that the maximum displacement (among all particles) is of order one coarse cell (i.e. ~ 0.64 h^{-1}Mpc). The use of 2LPT minimises the effects of transients (Crocce et al. 2006), while assuming a late starting redshift minimises discreteness errors (Michaux et al. 2020).

Simulations were performed with (an optimized version of) the parallel Adaptive Mesh Refinement (AMR) N-body code RAMSES 2 (Teyssier 2002), which makes use of a multigrid Poisson solver (Guillet & Teyssier 2011). A Triangular Shaped Cloud (TSC) assignment scheme was used (instead of the default Cloud-In-Cell assignment) such as to increase the isotropy

| Model | Ω_m  | σ_8   | w   |
|-------|------|-------|-----|
| ΛCDM | 0.25733 | 0.80101 | -1.0 |
| wCDM | 0.27508 | 0.85205 | -1.2 |

Table 1. Cosmological parameter values of the ΛCDM and wCDM simulated models respectively. The columns from left to right give the values of the cosmic matter density Ω_m, the linear root-mean-square fluctuations smoothed on the 8 h^{-1}Mpc scale σ_8, and redshift-independent equation of state w. In all models the baryon density is set to Ω_b = 0.04356, the density of the relativistic species is set to Ω_r = 0.00008, the curvature is set to Ω_k = 0, the reduced Hubble constant to h = 0.72, and the slope of the primordial spectrum n_s = 0.963.

Fig. 1. 1 and 2σ credible regions from the WMAP-7yr data analysis (beige filled contours) and the Planck primary CMB analysis of the TT, TE and EE anisotropy spectra (Planck Collaboration et al. 2020) (red and yellow filled contours). The parameter values of the ΛCDM and wCDM models correspond to the dot and the cross markers respectively.

https://bitbucket.org/rteissie/ramses/src/master/
of the gravitational field. The characteristics of the simulations are summarized in Table 2.

While storing all particles and gravity cells at all time steps would be ideal, in practice it is unbearable since it would over-\footnote{https://gitlab.obspm.fr/roy/pFoF}flow all the available storage devices (each snapshot occupies approximately 25 TB of memory). Therefore, we have opted for a hybrid strategy and stored from 40 to 50 redshift snapshots (depending on the simulated cosmological model). On the other hand, particles and gravity cells are also stored at every coarse time-step (thus ensuring good time resolution) in concentric shells located at the light-travel distance from an observer located at the center of the box at $z = 0$: these are the background light-cone data. We have saved three light-cones with different depths (with $z_{\text{max}} = 0.5$, 2 and 10 respectively) and apertures (full sky, 2500 and 400 deg$^2$ respectively) using the onion-shells techniques of Fosalba et al. (2008); Teyssier et al. (2009). Unlike many other studies, the maximum redshift $z_{\text{max}}$ of the cones is chosen in a conservative way to make sure that the comoving volume of the cone is smaller than the comoving volume of the simulation: this is required to minimize the effects of replica. The full-sky light-cone does not rely on any replica techniques, while the narrow light-cones are tilted with respect to the narrow light-cones are tilted with respect to the full-sky light-cone does not rely on any replica techniques, while simulation: this is required to minimize the effects of replica. The full-sky light-cone does not rely on any replica techniques, while

2.3. Relativistic ray-tracing and catalogue creation

To produce realistic observables, we use the ray-tracing framework MAGRATHEA-PATHFINDER (Breton & Reverdy, in prep.) based on the AMR library MAGRATHEA (Reverdy 2014), which computes the propagation of light rays within the 3D AMR structure of light-cones (such as the ones described in Sect. 2.2).

We consider a weakly perturbed FLRW metric given by

\[ g_{\mu\nu}dx^\mu dx^\nu = a(\eta)^2 \left[-(1 + 2\phi/c^2)c^2d\eta^2 + (1 - 2\phi/c^2)\delta_{ij}dx^idx^j\right], \]

with $\phi$ the gravitational potential, $\eta$ the conformal time, $x^i$ the comoving position and $c$ the speed of light. The integration is performed backward in time, starting from the observer at $z = 0$. Photons are initialised with $k^0 = 1$ and $k^\nu = 0$, where $k^\nu = (dn/d\lambda, dx^i/d\lambda)$ and $\lambda$ is the affine parameter. We interpolate the gravity information from the light-cone to the photon position using an inverse TSC scheme (so that to be consistent with the interpolation procedure used by the $N$-body solver) at the finest refinement level which contains the photon. If there are not enough neighbours at the same level, we perform an interpolation on a coarser grid and eventually repeat this procedure until we find enough neighbours to compute the interpolation. If we can not interpolate at the coarse level, the propagation stops (it means that the photon is out of the numerical light-cone). Once all the gravity information at the photon location has been evaluated, we solve the geodesic equations:

\[ \frac{d^2\eta}{d\lambda^2} = -\frac{2a'}{a} \frac{d\eta}{d\lambda} \frac{dn}{d\lambda} - \frac{2}{c^2} \frac{d\phi}{d\eta} \frac{dn}{d\lambda} + 2 \frac{\partial \phi}{\partial x^i} \frac{dx^i}{d\lambda} \frac{dn}{d\lambda}, \]

\[ \frac{d^2x^i}{d\lambda^2} = -\frac{2a'}{a} \frac{d\eta}{d\lambda} \frac{dx^i}{d\lambda} + \frac{2}{c^2} \frac{d\phi}{d\eta} \frac{dx^i}{d\lambda} - 2 \frac{\partial \phi}{\partial x^i} \frac{dn}{d\lambda}, \]

with $\phi$ the gravitational potential and $a' = da/d\lambda$ the time derivative of the scale factor. In particular, we use the precise value of $\partial \phi/\partial x^i$ estimated from the double-layer strategy adopted to build the light-cones, thus ensuring that the ISW-RS effect is correctly implemented even in the strongly non-linear regime.

Our method fully takes advantage of the adaptive mesh. In particular, we use an adaptive step equal to $1/4^{th}$ of the finest cell at the photon location. This allows for a precise light propagation in high-density regions.

To emulate what we really observe, we find the null geodesics connecting the observer to each individual source (DM particle, halo, etc.). To do so, we use the methodology described in Breton et al. (2019) which consists in the following steps. First, we launch a light-ray towards the comoving direction of the source. However, due to deflections induced by the matter density field, the photon will probably not hit the source.
Table 2. RayGal ΛCDM simulation parameters (wCDM simulation parameters are given in parenthesis when they differ): $L_{\text{box}}$ is the box length, $n_{\text{part}}$ is the number of particles, $n_{\text{ref}}$ the number of refinements, $m_{\text{ref}}$ the refinement threshold, $n_{\text{cell}}$ the final number of AMR cells, $m_{\text{p}}$ the particle mass, $\Delta_x$ the spatial resolution, $z_i$ the starting redshift, $C_{\text{dt}}$ is the Courant-like factor which determines the size of the integration time-step (with respect to the largest stable time-step) and $P_{\text{lin}}(k)$ specifies the source of the linear power spectrum used to generate initial conditions. All calculations have been performed in double precision.

| $L_{\text{box}}$ (h$^{-1}$Mpc) | $n_{\text{part}}$ | $n_{\text{ref}}$ | $m_{\text{ref}}$ | $n_{\text{cell}}$ | $m_{\text{p}}$ (h$^{-1}$M$_\odot$) | $\Delta_x$ (h$^{-1}$kpc) | $z_i$ | $C_{\text{dt}}$ | $P_{\text{lin}}(k)$ |
|-------------------------------|-------------------|-------------------|-------------------|-------------------|-----------------|-----------------|------|----------------|-----------------|
| 2625                          | 6.87 · 10$^4$     | 4096              | 7                 | 8                 | 4.41(4.46) · 10$^4$ | 1.88(2.01) · 10$^4$ | 5    | 46(51)        | 0.5             |

Fig. 2. Apparent matter overdensity within RayGal intermediate light-cone called "Narrow 2". This includes "all" weak-field relativistic contributions.

If that is the case, we then iterate on the initial conditions using a Newton-like method until the angle subtended by the source’s comoving position and the photon at the same distance is smaller than a given threshold (in our case, set to 10 milliarcsecond). Once the null geodesic connecting the observer and a source is found, we estimate all the contributions to the observed redshift at first-order in metric perturbations, accounting for local and integrated terms using either a linear decomposition of the redshift or its exact definition. We also provide several (partial) redshift definitions which progressively incorporate part of the relativistic effects in order to disentangle the various contributions:

$$z_0 = \frac{a_0}{a} - 1,$$  
$$z_1 = \frac{a_0}{a} \left( 1 + \frac{\phi_o - \phi_s}{c^2} \right) - 1,$$  
$$z_2 = \frac{a_0}{a} \left( 1 + \frac{v_s \cdot n}{c} + \frac{\phi_o - \phi_s}{c^2} \right) - 1,$$  
$$z_3 = \frac{a_0}{a} \left( 1 + \frac{v_s \cdot n}{c} + \frac{\phi_o - \phi_s}{c^2} + \frac{1}{2} \left( \frac{v_s}{c} \right)^2 \right) - 1,$$  
$$z_4 = \frac{a_0}{a} \left( 1 + \frac{v_s \cdot n}{c} + \frac{\phi_o - \phi_s}{c^2} + \frac{1}{2} \left( \frac{v_s}{c} \right)^2 - \frac{2}{c^2} \int_{\eta_s}^{\eta_o} \frac{d\eta}{c} \frac{d\phi}{d\eta} \right) - 1,$$  
$$z_5 = \left( \frac{g_{\mu\nu} k^\mu u^\nu}{g_{\mu\nu} k^\mu u^\nu} \right)_s - 1,$$

Although we implemented the possibility to give any peculiar velocity to the observer $v_0$, for simplicity we decide to set $v_0 = 0$ in this release.
where \( g_{\mu \nu} u^\mu u^\nu = -a c^0 \left( 1 + \phi/c^2 + v \cdot n/c + \frac{1}{2} (\xi^2) \right) \), the subscripts ‘o’ and ‘s’ denotes an evaluation at the observer and the source respectively, and \( z_n \) gives the different redshifts provided for each single source. \( z_0 \) is the comoving redshift (from background expansion), \( z_1 \) also includes gravitational redshift, \( z_2 \) includes the Doppler effect and \( z_3 \) adds the transverse Doppler effect. \( z_4 \) includes the contribution to the final redshift from all the effects including ISW-RS effect. \( z_5 \) is the exact redshift definition which should match \( z_4 \) (except for some small higher order contributions).

Furthermore, given the fact that the observed angular position of the source \( \theta \) is known, as well as the comoving angular position \( \beta \), then we can compute the deflection angle and evaluate the lensing distortion matrix \( \mathcal{A} \) along the true photon trajectory. This reads as:

\[
\frac{\partial \beta}{\partial \theta} = \begin{pmatrix} 1 - \kappa - \gamma_1 & -\gamma_2 + \omega \\ -\gamma_2 - \omega & 1 - \kappa + \gamma_1 \end{pmatrix},
\]

where \( \kappa \) and \( \gamma = (\gamma_1, \gamma_2) \) are the weak-lensing quantities related respectively to the convergence and shear, while \( \omega \) is the (small) image rotation. This matrix can be estimated using either an infinitesimal-beam or finite-beam methods (both are described in Breton & Fleury 2020). For the present release, we use the finite-beam method with a bundle semi-aperture of \( 10^{-5} \) radians (which corresponds for instance to the apparent angle of a ruler of comoving size \( \sim 10^{-1} \) kpc located at a comoving distance of \( \sim 1 \) h\(^{-1}\)Gpc in a flat universe). It is important to stress that there are two possible ways to define the beam cross-sectional area: perpendicular to the radial direction or perpendicular to the light-ray wave vector. Here we consider the second option (i.e. the so-called Sachs basis) which is more closely related to observable quantities: we account for the tilt of the cross-sectional area.

One has to be careful since the link between these lensing quantities and actual observables is not necessarily straightforward. The magnification \( \mu \) is directly given by the inverse of the determinant of the distortion matrix. For a comoving source, this gives the amplification of the flux by weak-lensing, where the flux is indeed an observable. In virtue of the distance-duality relation, \( \mu \) also provides the fractional change in the apparent area of the source where the area is also an observable. However for a non-comoving source, one should also account for redshift perturbations to evaluate the change in flux and area: this is called Doppler convergence (Bonvin 2008). The relative variation of the flux is given by the relative variation (induced by the redshift perturbations) of the square of the luminosity distance. These effects play a subdominant role at high redshift \((z>0.5)\) but may play a role at lower redshift. These subtleties are well described in Breton & Fleury (2020). Another observable in weak-lensing studies is the apparent shape of the sources (i.e. their ellipticity \( e \)). The average ellipticity is related to the reduced shear \( g = \gamma / (1 - \kappa) \) as \( < e > = < g > \) (if \( \kappa << 1 \) one finds \( < e > = < \gamma > \)).
shape is negligible. Textbooks often assume that the shear power spectrum and the gravitational convergence power spectrum are the same (thus highlighting the central role of the convergence in weak-lensing studies); while this is true at first order, we will discuss this point in this article. Finally, the orientation of the source is an observable which is a probe of the rotation. However it is a very subtle effect and it is also very challenging to know the original orientation of the sources. There are however some proposals using the polarisation of radiogalaxies (Francfort et al. 2021). Here we provide both the fundamental lensing quantities and the detailed redshift perturbations so that the user can reconstruct any physical/observable quantities of interest. In any case, the gravitational convergence \( \kappa \) play an important role since \( |\gamma| > \omega \) and the Doppler corrections are subdominant at \( z > 0.5 \), this is why we focus on this key quantity in this article.

Note that in the current implementation, we only detect one image per source. This is a valid approximation in the weak-lensing regime (although convergence and shear are not necessarily small). A possible extension of our work would be the use a multiple-root finder to account for multiple images. However, there are multiple reasons as to why the weak-lensing regime should still be a reasonable approximation for RayGal. First, for most practical cases the number of strong lensing events for galaxy-size lenses is small. Even if the probability to have strong-lensing events increase with redshift, for a realistic radial selection function the number of observable sources heavily decreases beyond \( z \approx 2 \sim 3 \). Second, strong lensing is usually relevant at very small angular scales, which is not necessary the focus of the present simulation. Third, when we perform source-averaging, the tail of the magnification’s PDF is damped with respect to the directional-averaging case (see e.g. Takahashi et al. 2011; Breton & Fleury 2020, and references therein). Moreover, this effect is further enhanced when using the finite-beam method (Fleury et al. 2017, 2019; Breton & Fleury 2020). Finally, even if strong lensing events occur, our geodesic finder would most likely find the principal image of the source.

2.4. Maps

Maps are built by projecting the matter distribution and its properties onto a sphere. We discretize the maps by considering the HEALPix pixelisation scheme (Hierarchical Equal Area isoLatitude Pixelisation, Górski et al. (2005)). The matter distribution can be weighed by radial selection functions of different type. Here, we generate two type of maps:

- Dirac radial selection maps: HEALPix maps generated assuming a Dirac selection function.
- Top hat radial selection maps: HEALPix maps generated assuming a top hat selection function.

Dirac radial selection maps are computed by stopping all the light-rays at a fixed comoving distance from the observer. The quantity of interest (for instance the distortion matrix) is then interpolated from the closest values on the light-cone. Top-hat radial selection maps are built from the relativistic catalogues. Particles (or halos) are selected within a shell of mean redshift \( z_{\text{mean}} \) and (half-)width \( \Delta z \). Particles (or halos) are then sorted according to HEALpix while keeping track of the empty pixels (no particles) and the masked pixels (outside of the cones). The surface overdensity is evaluated by computing the excess of surface density in pixels with respect to the mean surface density of the shell in the unmasked region. The distortion matrix is evaluated as an average over all particles. Empty cells are filled with the default undefined value provided by Healpix.

2.5. RayGal data: snapshots, light-cones, relativistic catalogues and maps

RayGal data are divided into four categories: snapshots, FLRW light-cones, relativistic catalogues and maps. Most of the RayGal data are available on the website of the COS team at LUTH.

Snapshots data (corresponding to particles at a given time) consist of:

- snapshots: all particles at a given time (position, velocity, identity),
- halo particles: all particles within halos (position, velocity, identity),
- halo properties: properties of all the halos (identity, number of particles, most-bounded particle position, center of mass position, mean velocity, maximum radius, moment of inertia, circular velocity, velocity dispersion, angular momentum, kinetic energy, self-binding energy, density profile, circular velocity profile).

FLRW light-cone data (corresponding to particles and cells near the past FLRW light-cone) consist of:

- particle light-cone: all particles just before or just after the past null light-cone (position, velocity, redshift),
- gravity light-cone: all gravity cells just before and just after the past null light-cone (position, potential, gravitational field, redshift).

These snapshot and light-cone data are built from the simulations and post-processing described in Sect. 2.2.

Relativistic catalogues (corresponding to sources as seen by the observer accounting for relativistic effects such as weak-lensing and RSD) consist of:

- halo catalogue (unlensed and lensed angular positions, background and perturbed redshifts (from Eq. (4) to Eq. (9)), weak-lensing distortion matrix, halo mass),
- particles catalogue: a random subset of dark matter particles (same properties as for the halo catalog except mass). They represent a population of sources with a bias \( b = 1 \).

These catalogues are built from the ray-tracing techniques described in Sect. 2.3.

Maps (corresponding to the projection of the matter distribution and its properties) consist of:

- Dirac radial selection maps (\( \kappa, \gamma_1, \gamma_2 \) and \( 1/\mu \), respectively the convergence, shear components and inverse magnification).

We provide Dirac radial selection maps for several redshifts within the range of our light-cones. Top hat radial selection maps (for \( \kappa, \gamma_1, \gamma_2 \) and \( \delta \)) can be computed from the released catalogues using HEALpix tools. For the narrow cones, pixels outside the footprint are masked. In that case, we only provide the relevant pixels within the angular selection function, therefore producing lighter files.

The characteristics of RayGal data are summarized in Table 3 and Table 4. An illustration of the apparent matter distribution and the various relativistic effects within the light-cone “Narrow 2” are shown in Fig. 2 and Fig. 3.\(^3\)\(^4\)\(^5\). In this cone,

\(^3\)https://cosmo.obspm.fr/public-datasets/

\(^4\)We have made use of Py-SPHViewer (Benitez-Llambay 2015) for the realisation of these images.
the source angular density (~ 40 arcmin⁻²) is similar to the one expected from present and future photometric surveys such as DES, KIDS, HSC, Euclid and LSST while the halo density (~ 10⁻³ h³ Mpc⁻³) is also similar to the one expected in spectroscopic surveys such as BOSS, eBOSS, DESI, Euclid and SKA.

2.6. Case study: configuration, definition, angular cross-spectra evaluation, analytical predictions

As already mentioned, in this work we present a case study application of the RayGAL light-cone datasets to the analysis of relativistic effects on the angular cross-spectra. In particular, we correlate the key quantity of clustering i.e. the matter overdensity δ and that of lensing i.e. the gravitational convergence κ using HEALPix maps. It is worth noting that these are not directly observable quantities (such as the galaxy overdensities or the galaxy ellipticities), nonetheless they are the central quantities in clustering and lensing studies from which one can deduce the correlation between observables. The goal here is not to focus on specific observables for a given survey, rather to provide general results about the imprint of relativistic effects on the density and lensing angular power spectra and cross-spectra.

2.6.1. Two-shells configuration

The matter overdensity and the gravitational convergence are averaged within 3D pixels defined by the radial extension of the shell and the HEALPix pixelisation scheme for the angular extension. The number of pixels is equal to $12 \times N_{\text{side}}^2$ and we have chosen $N_{\text{side}} = 4096$ for top-hat radial selection map. Given the number of sources in each shell, using a larger $N_{\text{side}}$ increases the number of empty pixels and the gain in precision is limited. For test maps under Born approximation, we have first computed a map with $N_{\text{side}} = 8192$ (resulting in a total number of light-rays of the same order of magnitude as the number of sources in catalogues shells) which was then degraded (i.e. each pixel is computed as an average over the 4 smaller pixels within it) down to $N_{\text{side}} = 4096$ so as to use the same resolution in all maps.

We consider two shells (1 and 2) extracted from the ΛCDM 2500 deg² light-cone. We isolate two possible redshifts for each shell: $z = 0.7 \pm 0.2$ and $z = 1.8 \pm 0.1$. We choose $z = 1.8$ since it is one of the largest possible redshift in the cone while the comoving distance to $z = 0.7$ is about half the comoving distance to $z = 1.8$, thus corresponding to a maximum of the lensing kernel for a source located at $z = 1.8$. Given that relativistic effects correlate distant shells, we investigate all the ten possible auto- and cross-power spectra for these two shells. We first investigate the clustering (3 density-density spectra), then the weak-lensing (3 convergence-convergence spectra) and finally, we investigate the galaxy-galaxy lensing (4 density-convergence spectra).

2.6.2. Relativistic effect definition

Weak-lensing as a relativistic effect has already been widely studied in the literature, especially under the Born approximation (i.e. by computing lensing quantities and in particular the convergence as an integral of the transverse laplacian along the undelected light-path). Henceforth, in the context of weak-lensing, we use as a reference case the convergence computed using the Born approximation ($\kappa_{\text{Born}}$). The mean Born convergence for a population of source galaxies (see Kilbinger 2015) is given by,

$$\kappa_{\text{Born}}(\theta) = \int_0^{\chi_{\text{lim}}} n(\chi) d\chi \int_0^{\chi_{S}} d\chi S^{\chi_S - \chi} \frac{\Delta_{\perp} \phi(\chi, a(\chi))}{c^2} \chi_S,$$

(11)

with $\chi$ the comoving distance (in a flat universe), $\chi_S$ the comoving distance of the source, $\chi_{\text{lim}}$ the limiting comoving distance of the galaxy sample, $n(\chi_S)$ the source probability distribution, and $\Delta_{\perp} \phi$ the laplacian perpendicular to the line of sight. We will consider a top-hat radial selection function (i.e. a shell). For a shell of volume $V_{\text{shell}}$ and constant density, $n(\chi_S) = 4\pi a^2 V_{\text{shell}} / \chi_S$. It is worth noting that a common additional approximation is to assume

$$\Delta_{\perp} \phi = \frac{3H_0^2 \Omega_m \delta}{2a},$$

(12)

with $H_0$ the Hubble constant. We do not make this assumption in our Born calculation. Moreover in this expression $\delta$ is often estimated within shells of typical size between 10 – 100 $h^{-1}$Mpc. Here we estimate $\Delta_{\perp} \phi$ at the resolution of the simulation (5-600 $h^{-1}$kpc). We have checked that using such approximations

| Data | $z$ | $z_i$ | 2.33 | 2.00 | 1.50 | 1.00 | 0.67 | 0.50 | 0.43 | 0.25 | 0.11 | 0.00 | other $z$ |
|------|-----|-------|------|------|------|------|------|------|------|------|------|------|-----------|
| Part. | x   | x     | x    | x    | x    | x    | x    | x    | x    | x    | x    | x    |          |
| Halos part. | x | x | x | x | x | x | x | x | x | x | x | x |          |
| Halos prop. | x | x | x | x | x | x | x | x | x | x | x | x |          |

Table 3. Data available for RayGAL snapshots in ΛCDM and wCDM cosmologies. We note that halo properties are available for about 30 to 40 "other $z$" per cosmology, but the redshifts may differ from one cosmology to another. $z$ is the redshift, $z_i$ the starting redshift, Part. stands for particles, prop. stands for properties.

| Type | charac. | $z_{\text{max}}$ | aperture (deg²) | gravity | part. | rel. cat. part(#) | rel. cat. halo (#) | double layer |
|------|---------|-----------------|-----------------|---------|------|-----------------|-------------------|-------------|
| Narrow 1 | 10.00 | 400 | x | x | $10^8$ | 2.5 $\times 10^9$ (on going) | x |          |
| Narrow 2 | 2.00 | 2500 | x | x | $3.5 \times 10^8$ | 1.2 $\times 10^7$ (1.3 $\times 10^7$) | x |          |
| Full sky | 0.48 | 41253 | x | x | $2 \times 10^8$ | 1.3 $\times 10^7$ (1.5 $\times 10^7$) | x |          |

Table 4. Data available for RayGAL light-cones in ΛCDM and wCDM cosmologies (wCDM simulation parameters are given in parenthesis when they differ). Charac. stands for characteristics. $z_{\text{max}}$ is the maximum redshift, aperture is the angular aperture, gravity indicates the presence of gravity information, part. the presence of particles information, rel. cat. part(#) indicates the number of particles in the relativistic catalogues, rel. cat. halo (#) the number of halos. Double-layer indicates the presence of two light-cones so as to compute time derivatives or perform time interpolation. The particles density in cone narrow 2 is similar to the galaxy density of present and future photometric survey while the halo density is similar to the galaxy density of present and future spectroscopic surveys.
lead to similar results in our article. A detailed study of the impact of these two approximations on various statistics would deserve a dedicated paper. Our reference is therefore an accurate Born convergence calculation along the undeflected path.

In the context of clustering or number count, our reference is the comoving matter overdensity \( \delta_{\text{com}} \). The overdensity is estimated as the local excess of particles (in real space) with respect to the mean matter density,

\[
\delta_{\text{com}}(\theta) = \frac{N_{\text{com}}(\theta)}{\langle N_{\text{com}}(\theta) \rangle} - 1,
\]

where \( N_{\text{com}}(\theta) \) is the number density of source. Here again, light-rays are assumed to propagate in straight-line. The Doppler effect can be considered as one of the standard effect in RSD studies (involving 3D correlation). However, the Doppler effect is often neglected in the context of angular correlation (see Grasshorn Gebhardt & Jeong 2020) as well as in weak-lensing and galaxy-galaxy lensing studies (see Ghosh et al. 2018).

We therefore call "relativistic effects" all the non-trivial GR effects beyond these two references (\( \delta_{\text{com}} \) and \( \kappa_{\text{Born}} \)) cases. To gain further understanding on the nature of relativistic effects we further decompose them in several pieces:

- Magnification bias effects (MB) are related to the decrease or increase of the apparent source overdensity due to weak-lensing magnification or demagnification as introduced by Turner et al. (1984). The apparent density is related to the comoving density by \( 1 + \delta = (1 + \delta_{\text{com}}) \mu^{-1} \mu_{s.5}^{-1} \) with \( \mu \) the magnification and \( s \) the logarithmic slope of the luminosity function of \( s = 0 \). This also biases the estimate of the convergence of a sample of galaxies as highly magnified region (with large convergence) are poorly sampled while demagnified region are very well sampled. Moreover, widely used source-weighted estimator are even more biased by this effect. We also include in this category other (subdominant) WL effects such as Post-Born effects related to the propagation of light which does not happen in straight-line.

- Redshift space distortions effects (RSD) are related to redshift perturbations which cause a change in the apparent density. This includes, Doppler effect, gravitational redshift effect, Transverse Doppler effect and ISW-RS effect. Note that lensing deflections effect are already included in MB.

All these effects do not exactly add up linearly. We therefore do not include them one by one (e.g. None, MB alone, RSD alone) but progressively (e.g. None, MB, MB+RSD). Note that even though the way to decompose the full signal in various components depends on which phenomenon we are interested in, the observed signal including all contributions is unique and well defined.

An illustration of the overdensity and convergence within the two shells and the importance of relativistic effects is shown Fig. 4 and Fig. 5.

2.6.3. Angular cross-spectrum estimator

The angular cross-spectra between two Healpix maps is estimated with PolSpice\(^7\) (Szapudi et al. 2001; Chon et al. 2004). The spectra are computed with fast Spherical Harmonic Transforms. They are corrected from angular selection function effects (i.e. mask effects) as well as pixel effect (i.e. deconvolution from

\[^{7}\text{http://www2.iap.fr/users/hivon/software/PolSpice/}\]

Fig. 4. Left: Overdensity map at \( z = 0.7 \) including relativistic effects. Right: Convergence map at \( z = 1.8 \) including relativistic effects. The size of the field extracted from cone "Narrow 2" is about 2500 deg\(^2\). A gnomonic projection has been used and the maps have been smoothed with a Gaussian beam of 10 arcmin FWHM for representation purpose. We note that some large overdensities at \( z = 0.7 \) can be seen in convergence map at \( z = 1.8 \).
Fig. 5. Relativistic contributions in the maps shown in Fig. 4. Top left: Relative difference between the overdensity maps at $z = 0.7$ with and without magnification bias (MB). Top right: Relative difference between the overdensity maps at $z = 0.7$ with and without redshift-space distortions (RSD). Bottom left: Relative difference between the convergence maps at $z = 1.8$ with and without MB effect. As expected the MB effect is anti-correlated with the value of the convergence. Bottom right: (Small) Relative difference between the convergence maps at $z = 1.8$ with and without RSD. Relativistic effects play a non-trivial role at the ten percents level in the density and convergence maps.

Since it removes the possible non trivial bias from the estimator in presence of a mask. In the context of weak-lensing and galaxy-galaxy lensing studies, we follow Schmidt et al. (2009). Since we use a pixel-based estimator we weight each $\kappa$ pixel with the density $1 + \delta$ (this is equivalent to an inverse variance weight). As shown in Appendix B, such weight allows a good match with the direct pair based estimator.
2.6.4. Angular cross-spectrum predictions (with CLASS)

Analytical predictions usually rely on the linear mapping assumption. Especially in the case of the Doppler contribution at small scale this is an approximation. However, non-linear corrections are less visible than in RSD studies because here we consider the angular power spectrum (which is indirectly sensitive to radial motions in a way that depends on the thickness of the shell). Therefore, under this assumption one can decompose the overdensity as

\[ \delta_i \approx \delta_i^{\text{comp}} + \delta_i^{\text{MB}} + \delta_i^{\text{RSD}}, \]

where \( \delta_i^{\text{comp}} \) is the comoving overdensity, \( \delta_i^{\text{MB}} \approx -2\kappa_i \) is the magnification-bias contribution dominated by the dilution term (\( \kappa_i \) is the gravitational convergence and we have assumed a logarithmic slope \( s = 0 \) for the source count in the context of our mass selected sample), and \( \delta_i^{\text{RSD}} \) is the contribution from redshift perturbations. In the context of source averaging (as in galaxy surveys) one can define an average convergence \(^9\) as

\[ \langle \kappa_i \rangle_s \approx \kappa_i^{\text{Born}} + \kappa_i^{\text{MB}} + \kappa_i^{\text{RSD}}, \]

where \( \kappa_i^{\text{Born}} \) is the convergence according to Born approximation, \( \kappa_i^{\text{MB}} = -2(\Delta^2)^{1/2} \) is the magnification bias contribution (assuming \( s = 0 \)) and \( \kappa_i^{\text{RSD}} \) is the contribution from redshift perturbation. More details as well as the expression of the angular spectra under the linear mapping assumption are provided in Appendix A.

By including relativistic effects in our simulations, we follow a strategy similar to that of studies of the Cosmic Microwave Background (CMB). The two most widely used CMB codes in the literature are CAMB (Lewis et al. 2000) and CLASS (Lesgourgues et al. 2011), which provide predictions for these effects (Challinor & Lewis 2011; Di Dio et al. 2013). Here, we confront our results to analytical predictions from the latter code, since by adjusting the namelist\(^{10} \) it automatically computes the ten cross-spectra we are interested in.

CLASS\(^11 \) is a linearized Einstein-Boltzmann solver, very accurate in the linear regime. It predicts lensing, density, and density-lensing angular power spectra without relying on Limber approximation. Lensing predictions are performed at first-order (Born without MB) and without RSD. However density and density-lensing predictions include MB and RSD (Doppler effect, gravitational redshift, ISW-RS). CLASS can also make predictions in the non-linear regime and we use them as our reference predictions. In the non-linear regime it relies on several assumptions such as:

- weak-lensing under Born approximation (MB cannot be accounted for and post-born effects are neglected)
- RSD with the linear mapping assumption from real space to redshift space and, approximate treatment of Doppler effect in the non-linear regime (i.e. no Finger-of-God effect).
- HALOFIT prescription (Takahashi et al. 2012) for the non-linear matter power spectrum \( P(k) \)

Using HALOFIT prescription induces up to 5% errors in the predicted matter power spectrum around \( k = 1 \) h Mpc\(^{-1} \) (Heitmann et al. 2014). The question of the error of \( P(k) \) due to the HALOFIT prescription is beyond the scope of this work, which is focused on relativistic effects. We therefore prefer to feed CLASS with a matter power spectrum interpolated from the RayGal suite. The precision of the fit becomes \( \sim 1\% \) between \( k = 0.002 \) h Mpc\(^{-1} \) and \( k = 20 \) h Mpc\(^{-1} \) (beyond which we still use HALOFIT prescription) for redshift between \( z = 0 \) and \( z = 2.33 \). Below \( k = 0.2 \) h Mpc\(^{-1} \), the effect of cosmic variance was reduced by subtracting the difference between the linear spectrum in the simulation (i.e. a specific realisation of initial conditions) and the linear spectrum from CAMB (i.e. ensemble average). Notice that at large wavenumbers we did not remove the shot noise because its effect was found negligible in the relevant range of scales for the current study (\( \ell < 5000 \)).

As we will see in the following, one of the main effect which cannot be captured by CLASS (beyond non-linear RSD at low redshift) is the effect of MB on convergence-convergence spectra and density-convergence spectra since it involves the bispectrum (\( \langle \kappa \kappa \kappa \rangle \)). To cross-check the validity of our results (which is obtained from an accurate but complicated ray-tracing procedure) we have computed from our Born maps, the absolute value of the inverse magnification \( |\mu_{\text{Born}}^{-1}| \). From this we have computed a (rough) overdensity map including MB and a (rough) convergence map including MB by weighting the comoving density and the Born convergence by \( |\mu_{\text{Born}}^{-1}| \). More precisely the approximate density and convergence maps are given by \( \delta_{\text{MB}}^{\text{weight}} = |\mu_{\text{Born}}^{-1}|(1 + \delta_{\text{comp}}) - 1 \) and \( \kappa_{\text{MB}}^{\text{weight}} = |\mu_{\text{Born}}^{-1}| \kappa_{\text{Born}} \). We have then computed the \( \langle |\mu_{\text{Born}}^{-1}| \delta_{\text{MB}} \rangle \) weight MB spectra by cross-correlating these maps. They are not analytical predictions but rather an estimate of the MB effect directly from the Born maps allowing for further cross-check of our ray-tracing results.

To conclude, we have computed the ten auto- and cross-spectra for two redshift shells both analytically and using the RayGal data. For each case we have computed a reference spectrum (comoving and/or Born), a lensed spectrum accounting for magnification bias correction (MB) and a relativistic spectrum accounting for both magnification bias corrections and relativistic redshift perturbations (MB+RSD). Additionally, we have computed a rough estimate of MB effect from Born inverse magnification maps: this \( \langle |\mu_{\text{Born}}^{-1}| \text{weight MB spectra} \rangle \) serves as a cross-validation of our MB results when analytical predictions are not available.

3. Results: analysis of density-lensing angular power spectra and cross-spectra (3×2 points)

Here, we present the results of the computation of the angular matter density and gravitational convergence auto- and cross-power spectra, \( C_{\delta\delta}; C_{\delta\kappa}; C_{\kappa\kappa} \), from the RayGal data.

3.1. Validation of the 3D cartesian real-space matter power spectrum

Although the real-space distribution is not the target of this study, we perform an analysis of the 3D matter power spectrum (computed from a snapshot of periodic-boundary-conditions simulations at a fixed redshift) as a test of robustness of the numerical analysis. First, we determine the range of validity of the matter power spectrum. Second, the evaluated matter power spectrum is used as input for our analytical predictions of relativistic effects.

We compute the 3D matter power spectrum in real space at \( z = 0 \) and \( z = 1 \) (for both the ΛCDM and wCDM runs) with the FFT-based parallel estimator POWERGRID (Prunet et al.

\(^{9}\) We omit the average in the following for clarity.

\(^{10}\) Beyond trivial modification of redshifts and cosmological parameters, we have set the parameter selection_tophat_edge=0.01 to ensure the top-hat selection profile has a sharp edge.

\(^{11}\) https://lesgourg.github.io/class_public/class.html
2008). The density is computed using a Cloud-In-Cell assignment scheme within a cartesian grid with 8192³ elements (the power spectrum is then deconvolved from the assignment window). The comparison with spectra from the emulator CosmEMU (Heitmann et al. 2016) shows a 1% agreement up to \( k = 1 - 2 \) h Mpc⁻¹ for both cosmologies (see Fig. 6). Notice that the location of the drop in power, due to finite mass resolution effect, is similar to that induced by baryonic physics and in particular Active Galactic Nuclei (AGN) feedback (Chisari et al. 2018) in cosmological simulations with hydrodynamics. It indicates that a higher resolution simulation would not necessarily improve matter power spectra predictions unless (costly) baryonic physics is properly and accurately taken into account (which is a non-trivial task). The increase in power near \( k = 7 - 10 \) h Mpc⁻¹ is due to both shot noise andaliasing which have not been subtracted. The oscillations at small wavenumbers are mostly related to sample variance: they are limited to the 2 - 3% level down to \( k = 0.02 \) h Mpc⁻¹ where linear theory starts to reach percent level precision. The percent level agreement between CosmEMU and RaGaL spectra over 2 decades of wave numbers (\( k = 0.02 \) to 2 h Mpc⁻¹) is a good cross-check of the precision of our real-space data.

### 3.2. Clustering: Density-density angular spectra

In this section, we focus on the angular matter clustering i.e. \( C_{\delta \delta}(\ell, z_1, z_2) \) for shells 1 and 2 at redshift \( z_1 \in [0.7, 1.8] \) and \( z_2 \in [0.7, 1.8] \) respectively.

#### 3.2.1. Comoving density

The comoving matter density angular auto- and cross-spectra are shown in Fig. 7, left panel. The spectra are binned with 30 bins in the multipole interval 30 ≤ \( \ell \) ≤ 5000. Symbols represent the mean value of the spectra in the bin, while the error bars represent the standard deviation of the spectra within the same bin. The continuous lines show the analytical predictions. The auto-spectra \( C_{\delta \delta}(\ell, z_1 = 0.7, z_2 = 0.7) \) and \( C_{\delta \delta}(\ell, z_1 = 1.8, z_2 = 1.8) \) show an excellent agreement with the CLASS analytical prediction across the entire multipole interval. At large scale (\( \ell < 50 \)), the fluctuations we see are very likely to be related to the finite size of the light-cone angular aperture (sample variance). The good agreement in the linear regime between \( \ell = 50 \) and \( \ell = 500 \) validates our simulation measurement. The non-linear regime begins near \( \ell \sim 500 \) corresponding approximately to \( k \sim 0.2 \) h Mpc⁻¹ at \( z \sim 1 \) where \( P(k) \) is known to deviate from linear theory at the ~10% level, see e.g. Rasera et al. 2014. As we have calibrated the \( P(k) \) used in the analytical predictions to that from the RaGaL simulation, the agreement still holds in the non-linear regime between \( \ell = 500 \) and \( \ell = 5000 \). We halt at \( \ell = 5000 \), which corresponds approximately to \( k \sim 2 \) h Mpc⁻¹ at \( z = 1 \), where finite resolution effects in our simulation (and possibly baryonic effects in the Universe) can no longer be neglected. Since the maximum \( \ell \) we consider is of order \( N_{\text{side}} \), we also expect the aliasing effect to be small. The green curve shows the cross-spectrum \( C_{\delta \delta}(\ell, z_1 = 0.7, z_2 = 1.8) \) which is completely negligible in real space both in numerical data and analytical prediction. This is because the shells are separated by about 1750 h⁻¹Mpc. The right panel shows the relative deviation from CLASS. It illustrates the agreement with the analytical prediction to be better than the 5% level and within error bars for the auto-spectra. The cross-spectrum lies outside the plot because of a division by a nearly zero CLASS prediction. Overall, this is a good cross-validation of CLASS and RaGaL’s random subset matter angular spectra.

#### 3.2.2. Relativistic effects

In Fig. 8, we plot the matter overdensity auto- and cross-spectra in the presence of the relativistic effects (upper left panel). We can see a noticeable change compared to the case without relativistic effects. shown in Fig. 7. The agreement between RaGaL measurements and CLASS prediction (including RSD and MB) is as good as before from the linear to the non-linear regime. The cross-spectrum between the \( z = 0.7 \) and \( z = 1.8 \) shells is now very different from zero: it reaches about 10% of the auto-spectra which is not negligible at all. This is due to weak-lensing that couples the clustering signal between two density shells: the density in the low redshift shell is a lens for the density of the high redshift shell. Here again there is a good agreement between predictions and simulations except below \( \ell = 50 \) where the simulation spectrum strongly underestimates the analytical
predictions. This is likely related to the limited aperture of the narrow light-cone which affects this subtle correlation.

The other panels allow us to investigate relativistic effects in more details: they show the relativistic contributions normalised by the CLASS spectra including all relativistic effects (we choose this normalisation since this is a smooth and non-zero spectrum in all our plots). The upper right and bottom left panels show the relativistic contributions to the auto-spectra. The MB contribution is mostly constant of order $+0.2$ at $z = 0.7$ and $-3\%$ at $z = 1.8$. This signature of lensing on the matter distribution is a subtle effect, well captured by RayGal, in good agreement with CLASS expectation from $\ell = 50$ to $\ell = 5000$. This effect has been investigated in several works (e.g. Fosalba et al. 2015 and reference therein). It is related to the so-called magnification bias where the apparent density becomes at (first order) $\delta_i = \delta_i^{\text{com}} + (5s - 2)\kappa_i$ (with $s$ the logarithmic slope of the source number count which is $s = 0$ for our mass limited sample, in this peculiar case it is also called dilution bias). As a consequence, there is an additional lensing contribution to the matter density angular power spectrum (see the second line of Eq. (A.2)) which can be simplified as:

$$C_{\delta,\delta}(l) \approx C_{\delta,\delta}^{\text{com}}(l) - 2C_{\delta,\kappa}(l) - 2C_{\kappa,\delta}(l) + 4C_{\kappa,\kappa}(l).$$  \hspace{1cm} (16)

The RSD contributions to the multipoles of the 3D galaxy-galaxy two-point correlation function is important in the linear regime (Kaiser effect which corresponds to an amplification of the clustering due to coherent motions plus a quadrupole and hexadecapole component) and in the non-linear regime (Finger-of-God effect which corresponds to a damping of the small-scale clustering due to incoherent motions). These contributions are however much smaller when using large spherical shells ($> 100 \ Mpc$) centered around the observer. Redshift perturbations mostly modify the apparent radial distance of the sources and therefore do not have a strong effect on the angular power spectra. There is however a subtle and non negligible amplification (see the first term of the third line of Eq. (A.2)) due to the Kaiser effect visible at large scale below $\ell \sim 100$. For the shell thickness we use, it can reach $5\%$ at $\ell = 20$ (for the $z = 0.7 \pm 0.2$ spectra) and $20\%$ at $\ell = 90$ (for the $z = 1.8 \pm 0.1$ spectra). While the geometry makes the effect non-trivial, it is well reproduced by the simulation on agreement with CLASS predictions. The MB effect is also well captured up to $\ell \sim 1000$ using our MB estimate based on Born inverse magnification weight (we will discuss the origin of the small discrepancy at large $\ell$ and low redshift in the lensing section). For both shells, the RSD effect is too small at large $\ell$ and we cannot see the damping behavior of the spectra. In Sect. 3.5.1, we have performed again the same exercise but at lower redshift, for narrower shells using the full-sky data. The damping of the angular spectra (related to Fingers-of-God effect) now becomes apparent and is not well reproduced by CLASS.

The bottom right panel shows the relativistic contribution to the density cross-spectrum between two shells. Because the real space spectrum is nearly zero, the relativistic contribution is compatible with $100\%$ for both CLASS and RayGal (between $\ell = 50$ and $\ell = 5000$). Note that we normalised the spectrum variation by the CLASS spectrum (even for RayGal spectrum). The good agreement between CLASS and RayGal means that the amplitudes of the total spectra including relativistic effects are close to each other. The amplitude is also in agreement with our MB estimate based on Born inverse magnification weight. Here again the relativistic effect can be understood following Eq. (16) where now the contribution of $C_{\delta,\delta}(l)$ becomes the dominant one compared to $C_{\kappa,\kappa}^{\text{com}}(l)$ and $C_{\kappa,\kappa}(l))$. It means that the matter cross-spectra between two widely separated shell is a good estimate of (-2 times) the density-convergence spectrum. We will now investigate these two spectra ($C_{\kappa,\delta}(l)$ and $C_{\kappa,\kappa}(l)$) in detail in the next subsections.

Overall, we conclude that it is important to consider both RSD and WL effects including all the corrections from the linear to non-linear regime; our simulations provide a good “laboratory” to test these effects by naturally including all these effects in a natural common framework.
Fig. 8. In these plots, diamonds are measurements from RAYGAL 2500 deg$^2$ lightcone while dashed lines are CLASS predictions. Top left: Matter-density angular auto-spectrum with relativistic corrections (MB density angular auto-spectrum $z = 0.7$) and $z = 1.8$ in $\Lambda$CDM cosmology. The opposite of the cross-spectrum between two shells at $z = 0.7$ and $z = 1.8$ is shown in purple. Top right: Relative deviation from comoving matter-density angular auto-spectrum at $z = 0.7$ in $\Lambda$CDM cosmology due to relativistic effects. The effects of the dilution term of magnification bias (i.e. $s = 0$) on the observed matter density spectrum is shown in green, while the effect of the dilution term of magnification bias (MB) plus RSD is shown in dark blue. An estimate of MB effect using an inverse magnification ($\mu_{\text{Born}}^{-1}$) weight is shown as light blue triangles (see text for details). Bottom left: Same but for $z = 1.8$ with MB effect in light-green, MB+RSD in orange, and $\mu_{\text{Born}}^{-1}$ weight MB estimate in green. Bottom right: Same but for the $z = 0.7 - z = 1.8$ cross-spectrum with MB in light blue, MB+RSD in purple and $\mu_{\text{Born}}^{-1}$ weight MB estimate in pink. Overall there is an impressive agreement with CLASS even though there is a combination of MB and RSD effects. For cross-spectrum relativistic effects largely dominate. These matter cross-spectra become sensitive probe of the density-convergence spectra.

3.3. Lensing: Convergence-convergence angular spectra

In this section we focus on the weak-lensing spectra i.e. $C_{\kappa\kappa}(\ell, z_1, z_2)$ for shells 1 and 2 at redshifts $z_1 \in \{0.7, 1.8\}$ and $z_2 \in \{0.7, 1.8\}$. We follow exactly the same methodology as for the clustering. We remind that we focus on the convergence defined from Eq. (10).

3.3.1. Born approximation

We investigate the gravitational convergence angular spectra under the Born approximation in Fig. 9. The spectra decrease with the multipole but now increase with redshifts (unlike the overdensity spectra). This is because the convergence is an integral of the overdensity (weighed by the lensing kernel) along the line of sight. A farther away source is therefore more distorted than a closer one. The cross-spectrum behavior is similar to the auto-spectra one since $\kappa$ is not a local quantity but an integrated one: all the shells are therefore correlated. Here again we find a good agreement between CLASS prediction and RAYGAL measurements in the linear and non-linear regime. The right panel showing the relative deviation between the two indicates that they are compatible within the error bars between $\ell = 50$ and $\ell = 2000$. The deviation below $\ell = 50$ is related to the limited angular size of the cone. Between $\ell = 2000$ and $\ell = 5000$ there is a $\sim 5 - 10\%$ deviation at low redshift, the simulation measurement is slightly higher than the prediction from CLASS. We are not sure of the origin of the deviation which might be related to shot noise. Despite such discrepancy at large $\ell$ which seems to vanish at large redshift, this provides a cross-validation of RAYGAL Born convergence maps and the CLASS predictions.

3.3.2. Relativistic effects

We now move to Fig. 10 which includes relativistic effects. The upper left plot shows a similar trend as with the Born approximation. However a careful inspection shows that the points have moved from above CLASS predictions to below. We now focus on the three other panels (upper right, bottom left and bottom right) which show the relative deviations from the Born conver-
Fig. 9. Gravitational convergence angular auto-spectrum in a single shell at $z = 0.7$ (red) and $z = 1.8$ (pink) in $\Lambda$CDM cosmology assuming Born approximation. The cross-spectrum between two shells at $z = 0.7$ and $z = 1.8$ is shown in green. Left: Spectrum from RayGal 2500 deg$^2$ lightcone (diamonds with error bars) and spectrum from CLASS (dashed line). Right: Relative deviation from CLASS prediction. Overall the measured power spectra are in agreement with CLASS predictions within the error bars except at large scale (small $\ell$) due to the finite area of the lightcone. We also note a shift at the $\sim 5$-10% level at large $\ell$ and low redshift which vanishes at larger redshifts.

Fig. 10. In these plots, diamonds are measurements from the RayGal 2500 deg$^2$ lightcone while dashed lines are CLASS predictions. Top left: Gravitational convergence auto-spectrum $C_{\kappa\kappa}$ with relativistic corrections (magnification bias and RSD) in a single shell at $z = 0.7$ (blue) and $z = 1.8$ (orange) in $\Lambda$CDM cosmology. The cross-spectrum between two shells at $z = 0.7$ and $z = 1.8$ is shown in purple. Top right: Relative deviation from gravitational convergence angular auto-spectrum (under Born approximation) at $z = 0.7$ in $\Lambda$CDM cosmology due to non-trivial relativistic effects. The full effects of magnification bias (MB, with $s = 0$) are shown in green, while the effect of RSD(+MB) is shown in blue. An estimate of MB effect using an inverse magnification ($\mu_{\text{Born}}^{-1}$) weight is shown as light blue triangles (see text for details). Bottom left: Same but for $z = 1.8$ with MB in light green, RSD(+MB) in orange and $\mu_{\text{Born}}^{-1}$ weight MB estimate in green. Bottom right: Same but for the $z = 0.7 - z = 1.8$ cross-spectrum with MB in light blue, RSD(+MB) in purple and $\mu_{\text{Born}}^{-1}$ weight MB estimate in pink. MB effects are not accounted for in CLASS and cause $\sim 10 - 30\%$ deviations. This confirms that the dominant effect is the dilution term of magnification bias related to source averaging (vs angular averaging).
gence spectra due to relativistic effects. It is interesting to note that RSD do not seem to play any role in both Class predictions and RayGal measurements. This is not trivial since redshift perturbations modify the apparent distribution of sources (and thus the observed densities). However, these changes do not affect the lensing itself since they are mostly radial. Instead, MB plays an important role on the convergence spectra which is not predicted by Class (Class relies on Born approximation, it can only account for the effect of MB on the overdensity but not on the convergence). The first contribution one can think of is the post-Born effect. These contributions are at the percent level and play a role mostly beyond \( \ell = 2000 \) (see e.g. Petri et al. 2017). The second (and main) contribution comes from (the dilution term of) magnification bias: magnified regions have fewer sources than demagnified ones. The decrease of the convergence spectra (computed from the observed position of sources) is not negligible at all since it grows from 5% to 25% between \( \ell = 100 \) and \( \ell = 5000 \). The decrease is also more important at larger redshifts. This is because the convergence is weighed by the density which itself is demagnified by lensing. At first order (see Eq. (15)), \( \delta = a^\text{Born}(1 + (5x - 2k^\text{Born}) \) (with \( s = 0 \) in our mass-limited sample), and as a consequence, the convergence two-point spectrum (see Eq. (A.5)) is approximated by

\[
C_{\kappa_1 \kappa_2}(l) \approx C_{\kappa_1 \kappa_2}^\text{Born}(l) - 2C_{\kappa_1 \kappa_2}^\text{Born}(l) - 2C_{\kappa_1 \kappa_2}^\text{Born}(l) + 4C_{\kappa_1 \kappa_2}^\text{Born}(l).
\]

The convergence spectrum depends on some \( \kappa^2 \) terms which are not necessarily small, especially at high redshifts.

Alternatively, it is possible to emulate such effect by using the Born approximation, and weighting the convergence by the inverse magnification for \( s = 0 \). This is what we call Born + Weight in Fig. 10. The trend is the same as with the catalogues, with small discrepancies at large \( \ell > 1000 \). These most likely come from the fact that the value of the magnification (computed with he Born approximation) is not exactly the same as the density ratio in a pixel between the lensed and unlensed matter distribution. However, this is a cross-check of the large effect due to lensing on convergence angular spectra.

Such a lensing bias has been investigated by Schmidt et al. (2009), who focused on the shear power spectrum and found similar trend (in their notation, \( q = 2 \) corresponds to the opposite site of our \( s = 0 \) correction). They found the correction to increase with \( \ell \) and with redshift. For a source at \( z = 1 \) the (norm of the) correction increase from 2% at \( \ell = 500 \) to 7% at \( \ell = 5000 \) in their article, while we find a correction about four times larger (at \( z = 0.7 \)). More recently the same trend was found but with smaller amplitude in Deshpande et al. (2020). Our result is not in contradiction with these findings since the effect of magnification bias is much stronger on the convergence than on the shear (see Appendix B). The origin of the lensing convergence bias is the same as the lensing shear bias: the magnified regions are less sampled than the demagnified ones leading to a bias. However, the magnification is directly related at first order to \( \kappa \) (and not to \( \gamma \)) and the effect on the convergence power spectrum is therefore larger. The bispectrum \( \langle \gamma \gamma \gamma \rangle \) is indeed much smaller than the bispectrum \( \langle \kappa \kappa \kappa \rangle \). An important consequence is therefore that the convergence power spectrum (or correlation function) can differ from the shear power spectrum (or correlation function) by up to 10 – 30% due to magnification bias.

To conclude, we have found that we reproduce basic weak-lensing results under the Born approximation and we capture non-trivial effects such as magnification bias which turn out to play an important role in the resulting spectra.

3.4. Galaxy-galaxy lensing: density-convergence angular cross-spectra

In this section we focus on the galaxy-galaxy lensing spectra i.e. \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1, z_2) \) for shells 1 and 2 at redshift \( (z_1, z_2) = (0.7, 1.8) \). We follow exactly the same methodology as for the clustering and the weak-lensing parts. Investigating galaxy-galaxy lensing in the non-linear regime is challenging since it involves non-trivial relativistic effects on both the overdensity and the convergence. To our knowledge an accurate study of such effects down to the non-linear regime is still lacking and we now try to fill in the gap.

3.4.1. Comoving density and Born approximation

The cross-spectra between the gravitational convergence (computed with Born approximation) and the (comoving) matter overdensity are presented in Fig. 11. Unlike for lensing and clustering there are now 4 cross-spectra since \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 0.7, z_2 = 1.8) \) is not equal to \( C_{\delta_{g_2 \delta_{g_1}}}(l, z_1 = 1.8, z_2 = 0.7) \). The dominant spectrum is the one with the overdensity at low redshift which acts as a lens for the convergence at high redshift, \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 0.7, z_2 = 1.8) \). This spectrum is in good agreement with the Class expectation. The cross-spectra with the density and the convergence at the same redshift \( C_{\delta_{g_2 \delta_{g_1}}}(l, z_1 = z_2) \) are smaller but non-zero. This is because our Born calculation accounts for the shell thickness. As a consequence, the density in the inner part of the shell acts as a lens for the convergence in the outer part of the shell. This contribution vanishes in the limit of infinitesimal shells (Dirac radial selection function). While the signal is clearly visible for the shell at \( z = 0.7 \), it becomes smaller and very noisy for the shell at \( z = 1.8 \) because the shell thickness is much smaller than the distance to the observer. Finally the non-trivial spectrum correlating the convergence at \( z = 0.7 \) with the density at \( z = 1.8 \), \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 1.8, z_2 = 0.7) \), is nearly zero both in RayGal and Class expectations. The right panel shows the relative deviation from Class predictions. Again, we observe a good agreement between the analytical prediction and the numerical data points from \( \ell = 50 \) to \( \ell = 5000 \) for the main spectrum \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 0.7, z_2 = 1.8) \). The deviations at lower \( \ell \) are related to sample variance. The spectrum \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 0.7, z_2 = 0.7) \) is noisy but compatible with Class within the error bars. The spectra \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 1.8, z_2 = 1.8) \) seems roughly in agreement with the expectation between \( \ell = 100 \) and \( \ell = 5000 \) but the oscillations are extremely large and can reach almost 100%. Finally the spectrum \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 1.8, z_2 = 0.7) \) is outside the range of the graph because of a division by nearly zero. Overall there is a good agreement between Class predictions and RayGal measurements.

3.4.2. Relativistic effects

We include relativistic effects in Fig. 12. The upper left panel shows that the 4 cross-spectra are now different from zero and they are even of the same order of magnitude (i.e. within a factor of ten in absolute value). Moreover, the order has changed since the second largest spectrum is now \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 1.8, z_2 = 1.8) \) which has been seriously boosted by relativistic effects. The most striking spectrum is \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 1.8, z_2 = 0.7) \) which is now of the same order as \( C_{\delta_{g_1 \delta_{g_2}}}(l, z_1 = 0.7, z_2 = 0.7) \) although

12 At first order, all the results can be compared by renormalising the correction so that \( 5s - 2 \to -2 \).
with a minus sign. Even though the changes are important, all the RayGal spectra seem at first sight in agreement with CLASS predictions (which include MB and RSD) within a few σ as we will see later. This is a good cross-check of the results. We now investigate the amplitude of relativistic effects to better understand the origin of the changes. The relativistic contributions in galaxy-galaxy lensing are presented in Ghosh et al. (2018) (using analytical predictions from CLASS). In their work and in all our panels the dominant effect is the magnification bias effect, which modifies the density (and in a more subtle way the convergence as shown previously). RSD are negligible here although they can not always be neglected since they play a (small) role at low redshift and low multipoles for some cross-spectra within thin shells (e.g. we have indeed checked that they are non-negligible but noisy contributions to C δδ(l, z1 = 0.45, z2 = 0.45) of order 10% for ℓ < 80). The dominant contribution is again magnification bias where the apparent density becomes (at first order) δ = δ0 + (5s − 2)κ, and the convergence becomes κ = κBorn(1 + (5s − 2)κBorn) (with s = 0 here). As a consequence, there is an additional lensing contribution in the cross-spectrum (see Eq. (A.6)):

\[ C_{\delta \kappa}(l) \approx C_{\delta \kappa}^{\text{Born}}(l) - 2C_{\delta \kappa}(l) - 2C_{\delta \kappa}(l) + 4C_{\delta \kappa}(l). \]  

The first two terms (as well as the RSD contribution) are included in CLASS but not the last two ones (nor the post-Born effects).

The relativistic contribution to C δδ(l, z1 = 0.7, z2 = 1.8) is presented in the bottom right panel. The dominant relativistic contribution is magnification bias with −15% between ℓ = 50 and ℓ = 500 and −20% between ℓ = 500 and ℓ = 5000. CLASS predicts a negative effect of order 10% beyond ℓ = 50. Given the size of the error bars, the deviation is of order 3σ below ℓ = 500 and 5σ above. The discrepancy is likely to be related to the effect of magnification bias on the convergence (i.e. the two last terms of Eq. (18)), which also decrease the k − κ cross-spectra (as seen in Sect. 3.3) and is not accounted for in CLASS. This is confirmed by our MB estimate from Born inverse magnification weight. In this configuration, the relativistic contributions to galaxy-galaxy lensing cannot be neglected. The other galaxy-galaxy lensing spectra are dominated by relativistic effects. The upper right panel shows the relativistic contributions to C δδ(l, z1 = 0.7, z2 = 0.7). This negative effect ranges from −50% to −100%. The shape is highly non-trivial with a bump near ℓ = 100, a minimum near ℓ = 1000 and another bump near ℓ = 5000. All these effects are well reproduced by CLASS (with deviations at the 2 − σ level) and our [μ−1] weight MB spectra below ℓ = 1000. The bottom left panel shows the contributions to C δδ(l, z1 = 1.8, z2 = 1.8) which are about +100% since C δδBorn(l, z1 = 1.8, z2 = 0.7) was small because of the small thickness of the shell. The relativistic contribution agrees with the CLASS prediction. Finally, as expected, the cross-spectrum C δδκ(l, z1 = 1.8, z2 = 0.7) is 100% explained by relativistic effects, and is compatible with the CLASS prediction (see Fig. 13). This non-trivial contribution can be understood using Eq. (18). It is dominated by −2C δδκ(l, z1 = 1.8, z2 = 0.7). The corresponding k − κ cross-spectrum presented in Fig. 10 is indeed very similar (when multiplied by a factor −2). For thin shells or when the density shell is beyond the convergence shell, it is therefore possible to probe lensing spectra from galaxy-galaxy lensing spectra. To conclude, the relativistic contributions to galaxy-galaxy lensing play an important role that cannot be neglected. The contributions of the magnification bias effect (on the density) are well captured by CLASS while we found additional contributions from the magnification bias (on the convergence). The actual impact of the magnification bias depends on the slope s, and the shell configurations, but it can give a 20 − 100% effect.

3.5. Evolution and cosmological dependence

3.5.1. Redshift evolution

We now investigate the redshift evolution of relativistic effects. We therefore perform the same analysis with two shells at low redshifts z1 = 0.225 ± 0.045 and z2 = 0.45 ± 0.025 extracted from the full-sky catalogue. The resolution of the Healpix maps built from the catalogue is Nside = 1024 while the resolution of the Born map is Nside = 2048. These maps are then degraded to Nside = 1024. The estimation of the power spectrum is straightforward since the cone is full-sky (i.e. no need of apodization to
Fig. 12. In these plots, diamonds are measurements from RayGal 2500 deg$^2$ lightcone while dashed lines are Class predictions. Top left: Matter density-gravitational convergence cross-spectrum with relativistic corrections (MB+RSD) in a single shell at $z = 0.7$ (blue) and $z = 1.8$ (orange) in $\Lambda$CDM cosmology. The (usual) cross-spectrum between two shells at $z = 0.7$ (density) and $z = 1.8$ (convergence) is shown in purple, while the (non-trivial) reverse one (cross-spectra between convergence at $z = 0.7$ and density at $z = 1.8$) is shown in green. Top right: Relative deviation from comoving matter density-Born gravitational convergence cross-spectrum at $z = 0.7$ in $\Lambda$CDM cosmology due to relativistic effects. Magnification bias (MB) is shown in green, while the effect of RSD(+MB) is shown in blue. An estimate of MB effect using an inverse magnification ($\mu_{\text{Born}}^{-1}$) weight is shown as light blue triangles (see text for details). Bottom left: Same but for the $z = 1.8$ with MB in green, RSD(+MB) in orange and $\mu_{\text{Born}}^{-1}$ weight MB estimate in pink. Relativistic corrections are between 50 and 100% for cross-spectrum at a single redshift. Overall there is a good agreement with Class at the 20% level. Here again the overestimation of the power-spectrum is related to the dilution term of the magnification bias effect on the convergence.

account for large masked region). We find that the global trend is similar to the one of high redshift measurements. There is also a good agreement with Class in most cases, while the deviations are well understood.

We now highlight the main differences between the high and low redshift cross-spectra – we illustrate some of them in Fig. 14, Fig. 15 and Fig. 16. It shows the impact of relativistic effects on three spectra. Fig. 14 shows the impact of relativistic effects on $C_{\delta\kappa}(l,z_1 = 0.225, z_2 = 0.225)$. We notice that the influence of magnification bias is now negligible while RSD plays a more important role. This is due to the weak-lensing effect which decreases with redshift. Class performs a good prediction at large scales; however, beyond $\ell \sim 100$ (corresponding roughly to $k \sim 0.15$ h Mpc$^{-1}$), the effects of RSD on the power spectrum become negative. As expected, this effect is not well reproduced by Class because of the assumption of linear mapping between real-space and redshift-space. Analytical predictions could be made using perturbation theory. A recent work by Grasshorn Gebhardt & Jeong (2020) about non-linear RSD in the harmonic space galaxy power spectrum finds similar trend thus reinforcing our claim of the damping of the angular matter power spectrum at large $\ell$ due to Fingers-of-God effect.

We now turn to the lensing power spectrum. We have checked that the agreement between the power spectrum of Born convergence map and Class expectation is better than 5%. The impact of relativistic effects on $C_{\kappa\kappa}(l, z_1 = 0.45, z_2 = 0.45)$ is illustrated in Fig. 15. RSD effects are still negligible. The effect of magnification bias is also much smaller being of order $\sim 5\%$ over a wide range of multipoles from $\ell \sim 10$ to $\ell \sim 400$. We have also noted that the magnification bias effect remains large (5 to 15%) for lensing cross-spectra.

We now investigate galaxy-galaxy lensing at low redshift. We have checked that trends are similar but the spectra are more noisy (and some sign changes occurred such as for $C_{\kappa\kappa}(l, z_1 = 0.45, z_2 = 0.45)$). The impact of relativistic effects on the overdensity-convergence power spectrum $C_{\delta\kappa}(l, z_1 = 0.225, z_2 = 0.45)$ is illustrated in Fig. 16. The magnification bias effect is negative of order $\sim 2\%$ to $\sim 5\%$ between $\ell = 100$ and $\ell = 1000$. The decrease is smaller than at higher redshift but still larger than the Class expectation (which ignores the MB effect on the convergence). RSD effects are small, however we
have noted that, according to CLASS and our (noisy) measurement, they contribute to \( \sim 10\% \) of \( C_{\delta\kappa}(\ell, z_1 = 0.45, z_2 = 0.45) \) for \( \ell < 80 \). While RSD seem negligible in most galaxy-galaxy lensing studies, they might play a role in some configurations: it is therefore important to consider all relativistic effects and to verify their relative amplitude before neglecting some of these effects. To conclude, at lower redshift the relative importance of RSD increases with respect to those of MB effects. It is also interesting to note that Finger-of-God effects are also visible within the angular power spectra.

### 3.5.2. Cosmological dependence

A detailed study of the full cosmological dependence of all cross-spectra and all relativistic effects is beyond the scope of this paper. Here we would like to broadly address the following questions: are the \( \Lambda CDM \) cross-spectra valid? What is the relative variation of the ten cross-spectra (including all relativistic effects) when changing cosmology from \( \Lambda CDM \) to \( wCDM \)? Can CLASS predict this relative variation in the non-linear regime? Do these spectra allow to discriminate between these two competitive scenarios both compatible with CMB constraints at the 2\( -\sigma \) level?

The analysis of the \( wCDM \) simulation is similar to the one of the \( \Lambda CDM \). We consider two shells at the same redshift and we build maps with the same resolution. The \( \Lambda CDM \) and \( wCDM \) cosmologies do not differ strongly since they are both calibrated on CMB data. As a consequence the relativistic effects behave qualitatively in a similar way and we therefore did not plot again the same figures as in \( \Lambda CDM \) cosmology. In Fig. 17, Fig. 18 and Fig. 19 we investigate the relative variation of the 10 density-convergence auto- and cross-spectra (including relativistic effects) when moving from \( \Lambda CDM \) to \( wCDM \). The first global remark is that there is a good agreement below \( \ell = 5000 \) between our results and CLASS calculation which is an encouraging validation of our work. In Fig. 17, the matter density auto-spectrum in \( wCDM \) cosmology differs from the one of \( \Lambda CDM \) cosmology
by $\sim -10\%$ near $\ell \sim 30$, $\sim 0\%$ near $\ell \sim 250$ and $\sim +10\%$ near $\ell \sim 3000$. The same trend can be found in the 3D matter power spectrum at $z = 1$ in Fig. 6. The relative variation of the cross-spectrum (which is dominated by relativistic effect) reach larger values of order $+20\%$ near $\ell \sim 5000$. All the dependence (including the non-trivial cross-spectrum) are well reproduced by CLASS (since the 3D power spectra were calibrated to RAYGAL simulations). In Fig. 18, the convergence power spectrum shows a larger relative difference of $15-25\%$ at $\ell \sim 30, 30-40\%$ at $\ell \sim 1000$ and $30\%$ at $\ell \sim 5000$. There is a good agreement with CLASS expectation up to $\ell \sim 500$. Beyond this multipole, the relative variation is overestimated by CLASS. This is likely to be related to the magnification bias effect, which is not included in the analytical prediction. The difference remains reasonable of order $10\%$. In Fig. 19, the density-convergence cross-spectra are presented. The cosmological dependence of the stronger signal $C_{\delta \kappa \ell} (\ell, z_1 = 0.7, z_2 = 1.8)$ (with smaller error bars in purple) rises from $0\%$ near $\ell \sim 40$ up to $\sim 20\%$ at $\ell \sim 1000$ and beyond. The agreement with CLASS is good at the 2-$\sigma$ level. The spectrum $C_{\delta \kappa \ell} (\ell, z_1 = 0.7, z_2 = 0.7)$ shows a similar trend rising from $0\%$ near $\ell \sim 100$ up to $\sim 20\%$ at $\ell \sim 2000$ and beyond. Finally the spectrum $C_{\delta \kappa \ell} (\ell, z_1 = 1.8, z_2 = 1.8)$ and $C_{\delta \kappa \ell} (\ell, z_1 = 1.8, z_2 = 0.7)$ dominated by relativistic effects show a larger variation rising from $20\%$ at $\ell \sim 30$ to $40\%$ near $\ell \sim 1000$ and beyond. It indicates that even though these spectra are noisier, they carry a strong cosmological signal. The cosmological dependence is well captured by CLASS for overdensity-convergence spectra.

To conclude, if one assumes that the cross-spectra are accurately known in $\Lambda$CDM, the cosmological dependence for the models in the vicinity of $\Lambda$CDM can be captured at first order by CLASS. To go further the modelling of MB and non-linear RSD should be improved. In any case, the cross-spectra carry complementary cosmological information (the cosmological dependences are different). For the studied $w$CDM and $\Lambda$CDM cosmologies, the weak-lensing power spectra and the galaxy-galaxy spectra dominated by relativistic effect seems the most sensitive probes followed by the relativistic matter power spectrum and the standard density-convergence spectrum. Relativistic $2 \times 2$ points spectra are therefore a promising cosmological probe.

4. Conclusion
In this work we have introduced a simulation suite for the study of relativistic effects in cosmology and illustrated its use with an application to the lensing-matter clustering statistics.

We have described the RayGalGroupSims (or in short RayGal) suite. This consists of two large and well resolved N-body simulations of two different cosmological models (ACDM and wCDM) calibrated on CMB data. For each simulation several
snapshots have been stored as well as (wide, intermediate or deep) particles and gravity light-cones. Halos have been detected in snapshots and light-cones according to a wide range of possible definitions. The specificity of this work lies in the relativistic ray-tracing technique used to generate the data: light-rays are propagated from the observer to the sources according to weak-field geodesic equations of general relativity. Several hundreds of million of particles and tens of million of halos have been replaced in redshift-space. Within our intermediate light-cone (2500 deg$^2$ up to $z = 2$), the source (or halo) angular densities are similar to the one expected from present and future photometric (or spectroscopic) surveys such as DES, KIDS, HSC, Euclid and LSST (or BOSS, eBOSS, DESI, Euclid and SKA). These relativistic particles/halos catalogues contain information about the lensing deflection angle, the weak-lensing distortion matrix, the apparent redshift including all contributions at first order in metric perturbation (comoving, Doppler, potential, transverse Doppler, ISW-RS). Relativistic HEALPix maps were also produced. All these catalogues and maps are publicly available.

The catalogues and maps are very generic: they allow a wide range of applications. We illustrate the strength of the approach with an application to the study of the lensing-matter clustering statistics which is a hot topic of modern cosmology. Since the matter overdensity and the gravitational convergence are the fundamental quantities of clustering and weak-lensing, we focus on the position-position, position-convergence and convergence-convergence $3 \times 2$pts correlations. The extension to more observable quantities such as the usual $3 \times 2$pts involving the shear instead of the convergence (see e.g. DES Collaboration et al. 2021) can be investigated in a future work. We consider two shells extracted from our intermediate light-cone: a low redshift shell ($z_1 = 0.7 \pm 0.2$) and a high-redshift shell ($z_2 = 1.8 \pm 0.1$). We compute the matter overdensity $\delta$ and gravitational convergence $\kappa$. We then evaluate the ten auto- and cross-spectra between overdensity and convergence at these two redshifts (including the non-trivial ones) up to $\ell = 5000$. Finally we investigate the relative amplitude of all the contributions beyond the standard one (evaluated from comoving overdensity $\delta_{\text{com}}$ and Born convergence $\kappa_{\text{born}}$): magnification bias (MB) and redshift-space distortions (RSD). These contributions are compared to CLASS predictions. Our main results are the following:

- **Validation**: There is an agreement at the few percents level between the standard cross-spectra (without relativistic effects) and CLASS predictions once the 3D real-space matter power-spectra is properly calibrated to the one of RayGal simulations (which itself is in agreement at the percent level with the one of CosmicEMU).

- **Clustering**: Both RSD and MB contribute to angular density spectra: MB is a nearly scale independent contribution at the $2 - 5\%$ level while RSD contribution is small for $\ell > 100-500$ (depending on redshift) but can reach $20-40\%$ at small $\ell < 20 - 100$. MB also correlates distant shells ($\sim 100\%$ contribution to the cross-spectra). In this configuration the matter cross-power spectrum becomes a sensitive probe of the density-convergence spectrum. The agreement with CLASS predictions (which include both MB and RSD) is excellent (at these redshifts but not at lower ones).

- **Weak-lensing**: The dominant effect is MB, whose contribution rises from $\sim 5 - 10\%$ to $\sim 30\%$ between $\ell = 200$ and $\ell = 5000$. MB is not included in CLASS. Since MB contribution to the shear power-spectrum is small it indicates that the gravitational convergence and shear power-spectrum can differ by $\sim 20 - 30\%$ at large $\ell$. The reason for the lensing bias is that highly magnified regions are less sampled than demagnified ones. However, the magnification is directly linked at first order to the convergence. The convergence is more correlated to itself than to the shear and thus the convergence lensing bias is much larger than the shear lensing bias. This bias can have observational implications for the interpretation of surveys probing sources of known size or sources of known luminosity.

- **Galaxy-galaxy lensing**: The dominant non-trivial contribution to overdensity-convergence cross-spectra is MB which plays a role on both the overdensity and the convergence. The comparison of cross-spectra from CLASS to $C_{\delta \kappa}(\ell, z_1 = 1.8, z_2 = 1.8)$, $\sim 50\%$ in $C_{\delta \kappa}(\ell, z_1 = 0.7, z_2 = 0.7)$ and $\sim 100\%$ in $C_{\delta \kappa}(\ell, z_1 = 1.8, z_2 = 1.8)$ and $C_{\kappa \kappa}(\ell, z_1 = 1.8, z_2 = 0.7)$. The three last cross-spectra are usually neglected in cosmological analysis (and in particular the last one) but their amplitude is not negligible compared to $C_{\delta \kappa}(\ell, z_1 = 0.7, z_2 = 1.8)$. For thin shells or when the density shell is behind the convergence shell the density-convergence cross-spectrum becomes a sensitive probe of the gravitational convergence power-spectrum. CLASS captures only the effect of MB on the overdensity. RSD are usually negligible but may play a role at the $\sim 10\%$ level at low $\ell$ for some specific configuration.

- **Redshift evolution**: At low redshift $z < 0.5$, we observe the same trends although MB plays a smaller role compared to RSD. Even though we consider angular spectra, Fingers-of-God effects are visible at large $\ell$ as a damping of the matter power spectra. These effects are not included in CLASS.

- **Cosmological dependence**: By changing the cosmology to wCDM we observe a relative variation of the 10 cross-spectra. However, the amplitude of the variation is different for each spectrum. For the specific model we consider, the largest variation is observed for convergence spectra and for the density-convergence spectra dominated by relativistic effects followed by the relativistic matter density cross-spectrum and the standard density-convergence spectrum. It indicates that relativistic $3 \times 2$pts spectra are powerful cosmological probes.

- **Correlation function**: There is a good agreement between the convergence angular correlation function estimated from convergence maps weighted by the observed density (i.e. inverse transform of the spectra presented in this article) and the direct pair-based estimate from catalogues. The agreement is not observed without density weight nor when removing the monopole/dipole. MB however plays an important role in all cases (including with a pixel-based estimate without a density weight).

The publicly available catalogues are very generic (they have not been built for a specific community, but instead from first principle). They may help to investigate any N-point cross-correlation between several observables (each of them being sensitive to a particular combination of relativistic effects). We identify some examples of applications of RayGal data but the reader can probably find many other. We also point to some illustrative articles on these topics that have already made use of RayGal data:

- **Galaxies (weak-lensing studies)**: extension of this work to shear and ellipticities, more realistic selection function, higher order statistics;

- **Galaxies (clustering and RSD studies)**: impact of relativistic effects on higher order statistics, impact on BAOs and two-points correlation functions (e.g. Breton et al. 2019; Di Dio

---

In the future, we plan to expand our source catalogue (galaxies, AGNs), to explore alternative cosmological models (modified gravity etc.), to extend our work to strong-lensing (i.e. by implementing a multiple root finder since our current version finds one image in the case of strong lensing), to consider alternative messengers (gravitational waves) and to investigate the role of baryonic physics. Relativistic ray-tracing is a promising tool of modern cosmology, it provides a natural framework to combine multiple cosmological probes, it may pave the way to shed light on the nature of the dark sector.

The document contains references to various works, but the main body of the text is not provided. The references are in the format of journal articles and preprints, and they cover a range of topics including cosmology, astrophysics, and dark matter. The authors mention the use of different methods and models to study the universe, from galaxy clusters to gravitational waves. The acknowledgments section thanks various contributors and organizations for their support. The references are cited using the American Astronomical Society (AAS) citation style.
Appendix A: Power spectra expressions under the linear mapping assumption

Under the linear mapping assumption (which is only used for analytical predictions), the matter overdensity \( \delta_i \) of a shell \( i \) can be decomposed as

\[
\delta_i \approx \delta_i^{\text{com}} + \delta_i^{\text{MB}} + \delta_i^{\text{RSD}},
\]

where \( \delta_i^{\text{com}} \) is the comoving overdensity, \( \delta_i^{\text{MB}} = \frac{1}{2} \delta_i^{\text{com}} - (1 + \delta_i^{\text{com}}) \approx -2 \kappa_i \) is the magnification bias contribution dominated by the dilution term (\( \mu_i \) is the magnification and we have assumed a slope \( s = 0 \)), and \( \delta_i^{\text{RSD}} \) is the contribution from redshift perturbations (see Breton et al. 2019 and reference therein). The matter density auto- and cross-power spectra are given by

\[
C_{\delta,\delta}(l) \approx C_{\delta,\delta}^{\text{com}}(l) + C_{\delta,\delta}^{\text{MB}}(l) + C_{\delta,\delta}^{\text{RSD}}(l),
\]

where \( C_{\delta,\delta}^{\text{MB}}(l) = C_{\delta,\delta}^{\text{com}}(l) + C_{\delta,\delta}^{\text{MB}}(l) \).

The convergence can be approximated at first order as,

\[
\kappa_i \approx \kappa_i^{\text{Born}},
\]

where \( \kappa_i^{\text{Born}} \) is the convergence according to Born approximation. However, in cosmological analysis, one needs to perform some averaging procedure to extract some statistics. While the above expression is recovered with direction averaging, it is not with source averaging (which is used in the analysis of observational data, in the calculation of power spectra and correlation functions). The average convergence depends on the apparent overdensity and is therefore sensitive to both magnification bias and RSD. The average becomes (\( \langle \kappa_i \rangle = \langle \Sigma_{\text{sources}} (1 + \delta_i) \rangle / \langle \Sigma_{\text{sources}} (1 + \delta_i) \rangle \) where \( \Sigma_{\text{sources}} \) is the sum over the sources. As a consequence, the (source) average convergence can be written as

\[
\langle \kappa_i \rangle_s \approx \kappa_i^{\text{Born}} + \kappa_i^{\text{MB}} + \kappa_i^{\text{RSD}},
\]

where \( \kappa_i^{\text{MB}} \) and \( \kappa_i^{\text{RSD}} \) are the magnification bias contribution (assuming \( s = 0 \), see Schmidt et al. 2009) and the RSD contribution, respectively.

In the following we will omit the average to make the equations more readable. The resulting power spectrum for the gravitational convergence can be expressed as,

\[
C_{\kappa,\kappa}(l) \approx C_{\kappa,\kappa}^{\text{com}}(l) + C_{\kappa,\kappa}^{\text{MB}}(l) + C_{\kappa,\kappa}^{\text{RSD}}(l),
\]

where the first line is the convergence power spectrum. The two-point statistics as in Sect. 3.3. This allows us to test the methodology used in this paper, based on the HEALPix map and angular power spectrum estimators.

To do so, we use the code ATHENA (Schneider et al. 2002). First, we have verified that the configuration-space measurement on the HEALPix map containing the convergence using the Born approximation gave the same results as its counterpart using POLSPICE.

In Fig. B.1, we show the relative difference between the measurements made on the catalogue containing the dilution bias with respect to Born at \( \epsilon = 1.8 \). We see that the measurements from ATHENA and POLSPICE agree extremely well, and yield a ~20% difference with respect to Born at the arcmin scale and ~50% at 100 arcmin. This confirms that the dilution bias has a strong impact on the convergence two-point statistics as in Fig. 10, where we used the same POLSPICE measurement. We note that, as we used POLSPICE and subtract the average and dipole to the data (which is common practice), the results would vary in practice, especially at larger angular scales. This most likely comes from the fact that when averaging over sources (which differs from averaging over directions), the signal decreases with angular scale, hence our results. Moreover we expect some leakage from small \( \ell \) to large and intermediate scales. It is interesting to see that there is already a ~10% discrepancy at 10 arcmin.

Finally, we show the relative difference when computing the cosmic shear. We see that in this case, the results are very close to the Born approximation. This shows that the very large effect of lensing bias mostly impacts the convergence, and only to a lesser extent the cosmic shear. This comes from the fact that the source-averaged convergence is zero (while the averaged shear is, neglecting intrinsic alignment) and the conver-
**Fig. B.1.** Relative difference between lensing angular 2PCF on the source catalogue accounting for the dilution bias and the Born convergence angular 2PCF. In red and green diamonds we show the measurements of cosmic shear and convergence 2PCF using Athena, while in blue and light blue we show the results using the same methodology as in Sect. 3, when keeping and removing the monopole and dipole respectively.

...ence three-point correlation function contribution is large (i.e. $\langle \kappa \kappa \kappa \rangle / \langle \kappa \kappa \rangle$ is larger than $\langle \gamma \gamma \kappa \rangle / \langle \gamma \gamma \rangle$).
