ABSTRACT: We explore the discovery potential of light gravitino mass $m_{3/2}$ by combining future cosmology surveys and collider experiments. The former probe the imprint of light gravitinos in the cosmic matter density field, whereas the latter search signatures of a supersymmetry breaking mechanism. Free-streaming of light gravitinos suppresses the density fluctuations at galactic and sub-galactic length scales, where weak gravitational lensing can be used as a powerful probe. We perform numerical simulations of structure formation to quantify the effect. We then run realistic ray-tracing simulations of gravitational lensing to measure the cosmic shear in models with light gravitino. We forecast the possible reach of future wide-field surveys by Fisher analysis; the light gravitino mass can be determined with an accuracy of $m_{3/2} = 4 \pm 1$ eV by a combination of the Hyper Suprime Cam survey and cosmic microwave background anisotropy data obtained by Planck satellite. The corresponding accuracy to be obtained by the future Large Synoptic Survey Telescope is $\delta m_{3/2} = 0.6$ eV. Data from experiments at Large Hadron Collider at 14 TeV will provide constraint at $m_{3/2} \simeq 5$ eV in the minimal framework of gauge-mediated supersymmetry breaking (GMSB) model. We conclude that a large class of the GMSB model can be tested by combining the cosmological observations and the collider experiments.
1 Introduction

Supersymmetry (SUSY) is one of the most attractive candidates of physics beyond the standard model. Minimal supersymmetric extension of the standard model (MSSM, see e.g. [1]) with \( \mathcal{O}(\text{TeV}) \) SUSY particles can possibly address several important issues in the standard model, such as the large hierarchy between the electro-weak scale and the grand unification scale, the existence of dark matter, and the origin of the cosmic baryon number. The MSSM is also known to achieve successful grand unification of the standard model gauge couplings at some high energy.

The null-detection of the SUSY particles so far suggests that SUSY is broken at some energy scale and mediated to MSSM via some messenger. Several mechanisms are proposed as the messenger such as gravity-mediated, anomaly-mediated, and gauge-mediated SUSY breaking (GMSB) models. GMSB models generally evade the flavor changing neutral current problem and the CP-problem, and thus they are thought to be the most interesting models.

Supergravity (SUGRA) as an extension of the global SUSY to the local one involves the superpartner of the graviton, which is referred to gravitino. The gravitino has helicity
3/2 and obtains the mass via the super-Higgs mechanism:

\[ m_{3/2} = \frac{\langle F \rangle}{\sqrt{3}M_{\text{pl}}}, \quad (1.1) \]

with the vacuum expectation value of \( F \)-term \( \langle F \rangle \) and the reduced Planck mass \( M_{\text{pl}} \simeq 2.43 \times 10^{18} \text{GeV} \). The gravitino is produced in the thermal bath immediately after the reheating of the Universe through the \( F \)-term suppressed interaction of goldstino component with spin \( \pm 1/2 \).

In the GMSB models, the gravitino mass is predicted to be in the range of \( m_{3/2} \simeq \text{eV} \text{–keV} \). The small \( F \)-term allows the gravitino to be in the thermal equilibrium until the decoupling of other SUSY particles. When the gravitino is decoupled from the thermal bath, it begins to stream freely and contributes as a “diffuse” matter component of the Universe. The gravitino free-streaming imprints characteristic features on the matter power spectrum, which are expected to be probed by observations of large-scale structure. For example, the current constraint of \( m_{3/2} < 16 \text{eV} \) is obtained by measuring the Ly-\( \alpha \) flux power spectra that essentially probe the distribution of the inter-galactic medium at high redshifts [2]. We note that the constraint is based on the crucial assumption that the distribution of the inter-galactic neutral gas traces the distribution of underlying dark matter even at nonlinear length scales. Gravitational lensing provides a direct physical mean of probing the distribution of total matter. For example, it has been suggested that cosmic microwave background lensing has a potential to probe the gravitino mass of \( m_{3/2} \simeq 1 \text{eV} \) in future experiments [3].

While the cosmological observations place an upper bound on the gravitino mass, the terrestrial collider experiments such as on-going Large Hadron Collider (LHC) give a lower bound through signatures of other SUSY particles (see Section 2). In the present paper, we show that essentially all the interesting range of the gravitino mass can be probed by combining the up-coming LHC run at 14 TeV and the near future weak lensing surveys by the Subaru Hyper Suprime-Cam (HSC) and the Large Synoptic Survey Telescope (LSST).

Gravitational lensing is one of the powerful tools to probe directly the matter distribution in the Universe. The coherent pattern of image distortion by weak lensing is called cosmic shear. Cosmic shear in principle can be induced by any foreground mass distribution along the line of sight regardless of its dynamical state or luminosity. Cosmic shear signals have been detected with high significance levels, and constraints on some basic cosmological parameters have been derived [4–7]. Upcoming weak lensing surveys such as HSC will cover a wide area extending more than a thousand square degrees. The surveys will also probe the matter distribution at \( \sim \text{Mpc} \) scale most accurately, where the imprints of the gravitino can be detected. It is therefore important and timely to study the effect of the light gravitino on cosmic shear. To this end, we run a set of cosmological \( N \)-body simulations to follow the nonlinear evolution of the matter density fluctuations with the imprints of the gravitino free-streaming. We then perform accurate ray-tracing simulations of gravitational lensing. We show that the cosmic shear is indeed a promising probe of the existence and the mass of the light gravitino.
The rest of the paper is organized as follows. In Section 2, we introduce the basics of the GMSB model. In particular, we clarify the relation between the gravitino mass and the masses of other SUSY particles. In Section 3, we discuss the linear evolution of the primordial density perturbation under the effect of the light gravitino. We present the resulting linear matter power spectra, which provides the initial conditions for our cosmological N-body simulations. In Section 4, we describe our simulation set-ups. In Section 5, we measure the cosmic shear power spectra from the simulations and forecast the discovery potential of the light gravitino in the future weak lensing surveys. The final section is devoted to the concluding remarks.

2 SUSY particle masses in the GMSB model

In the GMSB models [8–13], the SUSY breaking is mediated from the hidden sector to the MSSM sector via some messenger fields that are charged under the standard model gauge group. The gaugino and the sfermion masses are induced by the one-loop and the two-loop diagrams, respectively, at the leading order. Note that the gaugino and sfermion mass spectrum generically depends on the charge assignment to the messenger fields and that inadequate charge assignment might ruin the success of MSSM in the grand unification of the gauge couplings. A popular choice is to set messenger fields in complete multiplets of the \( SU(5) \) global/gauge symmetry. In the rest of this section, we consider specifically one of such models, the so-called minimal GMSB model.

The minimal GMSB model has the superpotential of

\[
W = (\lambda S + M) \sum_{n=1}^{N_5} \Phi_n \Phi_n^\dagger, \tag{2.1}
\]

where \( S \) is the goldstino superfields and \( M \) is the messenger mass. The \( F \)-term of the goldstino superfields develops the vacuum expectation values \( \langle F \rangle \), and the \( N_5 \) pairs of messenger superfields \( \Phi_n \) and \( \Phi_n^\dagger \) (\( n = 1, \ldots, N_5 \)) form the multiplets of \( 5 \) and \( \bar{5} \) of \( SU(5) \). In the minimal GMSB model, the gaugino mass is given by,

\[
M_a = \frac{g_a^2}{16\pi^2} \Lambda N_5 g(x), \tag{2.2}
\]

where the index \( a = (1, 2, 3) \) corresponds to the standard model gauge group \( U(1)_Y \times SU(2)_L \times SU(3)_C \), and \( g_a \) denotes the standard model gauge coupling. We normalize \( g_1 \) and \( g_2 \) such that \( g_1 = \sqrt{5/3} g' \) and \( g_2 = g \) with the conventional electro-weak gauge couplings \( g \) and \( g' \) (\( e = g \sin \theta_W = g' \sin \theta_W \); \( e \): positron charge, \( \theta_W \): Weinberg angle). The messenger scale \( \Lambda \) is defined by,

\[
\Lambda = \left| \frac{\langle F \rangle}{M} \right|. \tag{2.3}
\]

The function \( g(x) \) is given by,

\[
g(x) = \frac{1}{x^2} (1 + x) \ln(1 + x) + (x \to -x), \tag{2.4}
\]
and its argument is the dimensionless parameter \( x = |\Lambda/M| \). The sfermion mass squared is given by

\[
m_{\phi_i}^2 = 2\Lambda^2 N_5 \sum_{a=1}^3 C_a(i) \left( \frac{g_a^2}{16\pi^2} \right)^2 f(x),
\]

(2.5)

where the index \( i \) denotes fermion flavour and \( C_a(i) \) is the Casimir invariant. The function \( f(x) \) is given by,

\[
f(x) = \frac{1 + x}{x^2} \left[ \ln(1 + x) - 2\text{Li}_2 \left( \frac{x}{1 + x} \right) + \frac{1}{2} \text{Li}_2 \left( \frac{2x}{1 + x} \right) \right] + (x \to -x),
\]

(2.6)

with the dilogarithm function \( \text{Li}_2(x) \). In practice, we use the public code softsusy\[^{[14]}\]

to calculate the mass spectrum of SUSY particles numerically. The calculations take into account the renormalization group running of SUSY particle masses. The gravitino mass (eq. (1.1)) can be written in terms of the GMSB variables,

\[
m_{3/2} = \frac{\Lambda M}{\sqrt{3}M_\text{pl}|\lambda|} = \frac{\Lambda^2}{\sqrt{3}M_\text{pl}|\lambda|x}.
\]

(2.7)

From eqs. (2.2), (2.5) and (2.7), we can see that the SUSY particle masses are proportional to the square root of the gravitino mass, \( M_\phi \sim \Lambda \propto \sqrt{m_{3/2}} \). Therefore, collider experiments with higher energies can be used generally to search for signatures of heavier SUSY particles, which in turn give information on gravitinos with relatively larger masses. Note that, in high-energy collision of the standard model particles, the direct product is not gravitino with gravitational interaction, but other SUSY particles with gauge interaction. For example, in proton-proton collision experiments at the LHC, the colored SUSY particles (i.e. gluino and squarks) are important and directly related to the discovery potential for SUSY particles. Lighter gravitinos are associated with lighter colored SUSY particles that can be searched even with the current generation experiments.

In order to derive conservative constraints on the gravitino mass from the collider experiments, we consider models with maximal \( N_5 \) and \( |\lambda|x \). For the successful grand unification of the gauge couplings, the number of messenger \( N_5 \) needs to be at most five, \( N_5 \leq 5 \). We set \( N_5 = 5 \) as a conservative choice. The LHC current and future reach for the GMSB models is studied in detail in \[^{[15–23]}\]. Let us consider two focus points specifically, as summarized in Table 1. The ATLAS collaboration sets the lower bound on \( \Lambda > 51 \text{ TeV} \) with \( M = 250 \text{ TeV} \) and \( N_5 = 3 \) (10 + \( \tilde{10} \) of SU(5)) fixed from the events with at least one tau lepton and no light lepton in 21 fb\(^{-1}\) of LHC 8 TeV run \[^{[23]}\]. This can be interpreted as a lower bound on the gravitino mass \( m_{3/2} > 3 \text{ eV} \) through eq. (2.7), for the assumed perturbative coupling \( |\lambda| < 1 \).

It is expected that the \( \Lambda = 80 \text{ TeV} \) is accessible even for \( N_5 = 5 \) with the use of the multi-lepton modes in about 15 fb\(^{-1}\) of LHC 14 TeV run \[^{[19]}\]. The stability of the SUSY breaking vacuum requires |\lambda|x > 1.4 \[^{[24]}\]. An exciting implication of this is that virtually...
Table 1. Summary of the focus points for the GMSB model described in the text. The current focus point corresponds to the current lower bound on $\Lambda$ reported in [23]. In the future focus point, the GMSB parameters are set such that they minimize the gravitino mass for fixed $\Lambda$ while stabilizing the SUSY breaking vacuum. The future LHC reach is taken from [19].

| focus point | fixed GMSB parameters | LHC | $\Lambda$ | $m_{3/2}$ |
|------------|------------------------|-----|-----------|-----------|
| current    | $M = 250 \text{ TeV}, N_5 = 3, | 21 \text{ fb}^{-1} \text{ at } \sqrt{s} = 8 \text{ TeV} | \Lambda = 51 \text{ TeV} | m_{3/2} = 3 \text{ eV} |
| future     | $|\lambda| x = 1.4, N_5 = 5$ | 15 \text{ fb}^{-1} \text{ at } \sqrt{s} = 14 \text{ TeV} | \Lambda = 80 \text{ TeV} | m_{3/2} = 5 \text{ eV} |

all of the GMSB models with $m_{3/2} < 5 \text{ eV}$ can be probed in 15 fb$^{-1}$ of LHC 14 TeV run. Later in section 4, we show that the future weak lensing survey can determine the gravitino mass with an accuracy of $m_{3/2} = 4 \pm 1 \text{ eV}$, combined with the CMB anisotropy measurement by Planck satellite. We suggest that there is a good chance to test fundamentally the GMSB models in the near future.

3 Linear evolution of density perturbations with light gravitino

The light gravitino is in thermal equilibrium immediately after the reheating of the Universe unless the reheating temperature is extremely low [26]. When the cosmic temperature drops below the other SUSY particle masses, the decay and inverse-decay processes that have been keeping the thermal equilibrium between the light gravitino and the thermal bath, become inefficient. Then the light gravitino particles begins to stream freely with the momenta following the Fermi-Dirac distribution.

The gravitino contribution to the cosmic energy density is given by,

$$\Omega_{3/2} h^2 = 0.13 \left( \frac{g_{3/2}}{2} \right) \left( \frac{m_{3/2}}{100 \text{ eV}} \right) \left( \frac{g_{*3/2}}{90} \right)^{-1}$$

(3.1)

where $g_{*3/2}$ is the effective massless degrees of freedom for the cosmic entropy at the time of gravitino decoupling. The exact value of $g_{*3/2}$ depends on the mass spectrum of the SUSY particles (e.g. $\Lambda$) [3, 27]. However, its weak dependence allows us to fix $g_{*3/2} = 90$ without changing our results by more than 5%. It should be noted that the effective internal degrees of freedom of gravitino is not $g_{3/2} = 4$, but $g_{3/2} = 2$. This is because only goldstino component (spin ±1/2) can interact with the thermal bath through the $1/\langle F \rangle$ suppressed interactions.

From the above formula, we find that the light gravitino with $m_{3/2} \lesssim 100 \text{ eV}$ (of our interest here) cannot account for the cosmological dark matter mass density. We assume that some cold and stable particle makes up the rest of dark matter, i.e.,

$$\Omega_{\text{dm}} = \Omega_{cs} + \Omega_{3/2}.$$  

(3.2)

Such a cold and stable particle can be the QCD axion [28–30] or the composite baryons in the SUSY breaking, or can also be generated in the messenger sector in models with strongly coupled low scale gauge mediation [31–34].
The free-streaming of light gravitino affects the evolution of primordial density perturbations in a similar manner as the standard model neutrinos do. We discuss the similarity and indeed the degeneracy of the effects of the light gravitino and the standard model neutrinos later in Section 5. The suppression owing to free-streaming occurs below a cut-off scale that is characterized by the Jeans scale at the matter-radiation equality \( a_{eq} \):

\[
k_3 = a \sqrt{\frac{4\pi G \rho_M}{\langle v^2 \rangle}} \bigg|_{a=a_{eq}} \simeq 0.86 \text{ Mpc}^{-1} \left( \frac{g_{3/2}}{2} \right)^{-1/2} \left( \frac{m_{3/2}}{100 \text{ eV}} \right)^{1/2} \left( \frac{g_{s\nu} s}{90} \right)^{5/6},
\]

where \( G \) is the Newton’s constant and \( \rho_M \) is the total matter density of the Universe. The mean square velocity \( \langle v^2 \rangle \) is evaluated over the whole dark matter mass distribution function \( f_{dm}(v) \) \( \int d^3v f_{dm}(v) = \rho_{dm} \). It means \( \langle v^2 \rangle = f_{3/2} \langle v^2 \rangle_{3/2} \) effectively, where \( f_{3/2} \) is the gravitino density fraction \( \left( f_{3/2} \equiv \Omega_{3/2}/\Omega_c \right) \) and \( \langle v^2 \rangle_{3/2} \) is the mean square velocity of the gravitino particles. The resultant linear matter power spectrum is shown and compared with that of the standard ΛCDM model in Figure 1.

Before discussing the details of the matter power spectrum, let us briefly consider the effect of some non-standard thermal history of the Universe. The overall influence of the light gravitino on the cosmic expansion can be basically characterized by one parameter, the gravitino mass \( m_{3/2} \). This is because the gravitino temperature of the Fermi-Dirac distribution can be related to the observed CMB temperature through entropy conservation, i.e. \( g_{s\nu} s_{3/2} \simeq 90 \). However, non-standard thermal history with, e.g., entropy production \([36]\), can change \( g_{s\nu} s_{3/2} \) drastically to \( g_{s\nu} s_{3/2} \simeq O(1000) \). Then cosmological constraint on \( m_{3/2} \) can be significantly altered, or the constraint needs to be re-interpreted within a suitable class of models. In the following discussion, we consider the standard thermal history with \( g_{s\nu} s_{3/2} = 90 \), and hence \( m_{3/2} \) is the single model parameter.

We calculate the evolution of the linear density perturbations \( \delta \) by modifying CAMB \([37]\) suitably. In Figure 1, we plot the dimensionless matter power spectra \( \Delta(k) \) defined by

\[
\langle \delta(x)\delta(y) \rangle = \int d\ln k \Delta(k) e^{i k \cdot (x-y)},
\]

for mixed dark matter models with \( m_{3/2} = 0 \) (cdm), 4, and 16 eV. We adopt the cosmological parameters of the Planck mission first year results \([38]\). The free-streaming effect appears clearly at small length scales (eq. 3.3) but the suppression below the cut-off scale is more significant for models with heavier gravitino (compare \( m_{3/2} = 4 \text{ eV} \) and 16 eV in Figure 1). This is because larger \( m_{3/2} \) gives a larger fractional contribution to the total matter density as \( f_{3/2} \propto m_{3/2} \). We thus expect that models with heavy gravitino can be constrained by observations of large-scale structure of the universe.

4 Weak gravitational lensing

4.1 Lensing power spectrum

We summarize basics of gravitational lensing by large-scale structure. When one denotes the observed position of a source object as \( \theta \) and the true position as \( \beta \), one can characterize
Figure 1. Linear dimensionless matter power spectra for \( m_{3/2} = 0 \) (cdm), 4, and 16 eV. We adopt basic cosmological parameters given by the Planck mission first year results [38]. The vertical lines represents the cut-off scales of eq. (3.3).

the distortion of image of a source object by the following 2D matrix:
\[
A_{ij} = \frac{\partial \beta^i}{\partial \theta^j} \equiv \begin{pmatrix}
1 - \kappa - \gamma_1 & -\gamma_2 \\
-\gamma_2 & 1 - \kappa + \gamma_1
\end{pmatrix},
\]
where \( \kappa \) is convergence and \( \gamma \) is shear. In weak lensing regime (i.e. \( \kappa, \gamma \ll 1 \)), each component of \( A_{ij} \) can be related to the second derivative of the gravitational potential \( \Phi \) [39, 40] as
\[
A_{ij} = \Phi_{ij} - \delta_{ij},
\]
\[
\Phi_{ij} = 2 \frac{c^2}{H_0} f_{\rho_0} \int_0^\chi d\chi' g(\chi, \chi') \frac{\partial^2}{\partial x_i \partial x_j} \Phi[\rho(\chi') \theta, \chi'],
\]
\[
g(\chi, \chi') = \frac{r(\chi - \chi')}{r(\chi)}.
\]
where \( \chi \) is comoving distance, \( r(\chi) \) is angular diameter distance, and \( x_i = r\theta_i \) represents physical distance. By using the Poisson equation, one can relate the convergence field to the matter overdensity field \( \delta \) [39, 40]. Weak lensing convergence field is then given by
\[
\kappa(\theta, \chi) = \frac{3}{2} \left( \frac{H_0}{c} \right)^2 \Omega_{m0} \int_0^\chi d\chi' g(\chi, \chi') \frac{\delta[r(\chi') \theta, \chi']}{a(\chi')}.
\]
In this paper, we use the convergence power spectrum to constrain the gravitino mass. With the flat sky approximation, which is sufficient for angular scales of our interest, the Fourier transform of convergence field is defined by
\[
\kappa(\ell) = \int \frac{d^2 \ell}{(2\pi)^2} e^{i \ell \cdot \theta} \tilde{\kappa}(\ell).
\]
The power spectrum of the convergence field $P_\kappa$ is defined by
\[
\langle \tilde{\kappa}(\ell_1)\tilde{\kappa}(\ell_2) \rangle = (2\pi)^2\delta_D(\ell_1 - \ell_2)P_\kappa(\ell_1),
\]
where $\delta_D(\ell)$ is the Dirac delta function. By using Limber approximation [41, 42] and eq. (4.5), we obtain the convergence power spectrum as
\[
P_\kappa(\ell) = \int_{\chi_s}^{\chi_0} d\chi \frac{W(\chi)^2}{r(\chi)^2} P_\delta \left( k = \frac{\ell}{r(\chi)}, z(\chi) \right),
\]
where $P_\delta(k)$ is the three dimensional matter power spectrum, $\chi_s$ is comoving distance of source galaxies and $W(\chi)$ is the lensing weight function defined as
\[
W(\chi) = \frac{3}{2} \left( \frac{H_0}{c} \right)^2 \Omega_{\text{m0}} \frac{r(\chi_s - \chi) r(\chi)}{r(\chi_s)} (1 + z(\chi)).
\]

The non-linear gravitational growth of $P_\delta(k)$ significantly affects the amplitude of convergence power spectrum for the angular scales less than 1 degree [43–45]. Typical weak lensing surveys are aimed at measuring the cosmic shear at angular scales larger than a few arcmin, corresponding to a few mega-parsec. Therefore, accurate theoretical prediction of non-linear matter power spectrum is essential to derive cosmological constraints from weak lensing power spectrum. Several analytic models are available that accurately predict the non-linear evolution of $P_\delta(k)$ for the standard $\Lambda$CDM universe [46–49]. Unfortunately, there are no calibrated fitting formulae of $P_\delta(k)$ for the mixed dark matter models we consider here. We thus use direct numerical simulations to obtain the convergence power spectra.

### 4.2 Cosmological simulations

#### 4.2.1 $N$-body simulations

It is necessary to use ray-tracing simulations in order to study the effect of light gravitino on the weak lensing power spectrum in nonlinear regimes. We first run cosmological $N$-body simulations for models with light gravitinos. We use the parallel Tree-Particle Mesh code Gadget2 [50]. Each simulation is run with $512^3$ dark matter particles in a volume of comoving 240 Mpc/$h$ on a side. We generate the initial conditions following the standard Zel’dovich approximation. We use the accurate linear matter power spectrum calculated by the modified CAMB (Section 3). It is important to generate the initial conditions at a sufficiently low redshift so that the total matter, including the contribution from the light gravitino, can be treated as effectively a cold component. We set the initial redshift $z_{\text{init}} = 9$ because the typical thermal velocity of the gravitino is then sufficiently small compared to the virial velocity of the smallest halos resolved in our simulation. We also run a $N$-body simulation from $z_{\text{init}} = 49$ for the mixed dark matter model to examine the overall effect caused by the choice of $z_{\text{init}}$.

For our fiducial cosmology, we adopt the following parameters: matter density $\Omega_m = 0.3175$, dark energy density $\Omega_\Lambda = 0.6825$ with the equation of state parameter $w_0 = -1$, Hubble parameter $h = 0.6711$ and the primordial spectrum with the scalar spectral index
\[ m_{3/2} \, [\text{eV}] \quad \text{init} \quad \# \text{ of } N\text{-body sims} \]

| Model          | \( m_{3/2} \) | \( z_{\text{init}} \) | \# |  |
|----------------|--------------|----------------|----|---|
| CDM            | 0            | 49             | 5  |   |
| MDM4–lowz      | 4            | 9              | 5  |   |
| MDM16–lowz     | 16           | 9              | 5  |   |
| MDM4–highz     | 4            | 49             | 5  |   |
| MDM16–highz    | 16           | 49             | 5  |   |

Table 2. Parameters for our \( N \)-body simulations. For each model, we run 5 \( N \)-body realizations and generate 20 weak lensing convergence maps.

\( n_s = 0.9624 \) and the normalized amplitude \( A_s = 2.215 \times 10^{-9} \) at the pivot scale \( k = 0.05 \text{ Mpc}^{-1} \). These parameters are consistent with the Planck mission first year results \cite{38}. Two cases with the gravitino mass \( m_{3/2} = 4 \) and 16 eV are chosen as representative models. We summarize the simulation parameters in Table 2.

### 4.2.2 Ray-Tracing simulation

We generate light-cone outputs from our \( N \)-body simulations for ray-tracing simulations of gravitational lensing. The simulation boxes are placed to cover a past light-cone of a hypothetical observer with angular extent \( 5^\circ \times 5^\circ \), from redshift \( z = 0 \) to \( z \sim 1 \), similarly to the methods in \cite{51,52}. We use the standard multiple lens plane algorithm in order to simulate gravitational lensing signals \cite{43}. The configuration of our simulations is similar to that in \cite{45}.

We set the initial ray directions on \( 4096^2 \) grids. The corresponding angular grid size is \( 5^\circ/4096 \sim 0.075 \text{ arcmin} \). To avoid multiple appearance of the same structure aligned along a line-of-sight, we shift randomly the \( N \)-body simulation boxes. In addition, we use simulation outputs from independent realizations when generating the light-cone outputs. Finally we obtain 20 independent convergence maps from 5 \( N \)-body simulations for each cosmological model. We fix the redshift of the source galaxies to \( z_{\text{source}} = 1.0 \).

We measure the binned power spectrum of convergence field by averaging the product of Fourier modes \( |\tilde{\kappa}(\ell)|^2 \) for each multiple bin with \( \Delta \log_{10} \ell = 0.1 \) from \( \ell = 100 \) to \( 10^5 \).

### 5 Results

#### 5.1 Convergence power spectrum

Let us first discuss how the light gravitino affects the lensing power spectrum. Figure 2 compares the measured convergence power spectra with the analytic model prediction (eq. (4.8)) calculated by the fitting model in \cite{49}. The results for \( m_{3/2} = 0.4 \) and 16 eV are shown in the left, medium and right panel, respectively. The red points show the average power spectrum over 20 realizations with the error bars indicating the standard deviation of the realizations. The solid line is the model prediction of eq. (4.8) for \( z_{\text{source}} = 1 \). Note that the fitting function for \( P_\delta(k) \) is calibrated for the standard \( \Lambda \text{CDM} \) cosmologies with a wide range of cosmological parameters. We thus assume that the non-linear evolution
Figure 2. The convergence power spectra from our ray-tracing simulations for models with $m_{3/2} = 0, 4$ and 16 eV are shown in the left. In each panel, the red points represent the average measured power spectrum and the error bars show the standard deviation over 20 realizations. We use the simulations that start from $z_{\text{init}} = 9$ for this figure. The solid line is calculated by eq. (4.8) and fitting formula of $P_{\delta}(k)$ in [49] with $z_{\text{source}} = 1.0$.

of $P_{\delta}(k)$ for our mixed dark matter model is also described in the same manner as in the standard $\Lambda$CDM. In practice, we simply input the linear power spectrum for the mixed dark matter model (Section 3), but do not change the coefficients in the formula.

We see in Figure 2 that the analytic model and the simulation result agree well to $\ell \leq 4000$. This is consistent with the results of previous studies [45, 49]; the fitting model becomes less accurate at (sub-)arcminute scales even in the case of standard $\Lambda$CDM cosmology. The convergence power spectra for the mixed dark matter model differ significantly from that for the $\Lambda$CDM model even at around $\ell = 1000$ corresponding to physical megaparsec scale. Clearly, free-streaming of the gravitino affects the matter power spectrum at the nonlinear scales, and thus the above simple analytic approach does not work well even at $\ell = 1000$ for the mixed dark matter model.

We have examined the effect of choice of the initial redshift. In general, $N$-body simulations for the kind of mixed dark matter model should be initialized at a sufficiently low redshift in order to avoid numerical effects owing to gravitino thermal motions. Because assigning thermal velocities to $N$-body simulation particles is a non-trivial issue (see, e.g., [53]), we do not attempt to add random velocities to the particles. Instead, we examine how the choice of initial redshift affects the result at low redshifts by comparing two simulations that are started from $z_{\text{init}} = 9$ and 49. Figure 3 compares the lensing power spectra obtained from our simulations with different $z_{\text{init}}$.

The red points are for the gravitino with $m_{3/2} = 4$ eV and the blue points for $m_{3/2} = 16$ eV. Note that, unlike in ordinary warm dark matter models, the free-streaming scale, the
Figure 3. We plot the ratio of the lensing power spectra of the ray-tracing simulations with \( z_{\text{init}} = 9 \) and 49. The error bars indicating standard deviation estimated from 20 realizations.

gravitino mass, and the cosmic abundance are all related to each other in our light gravitino model. We plot the standard deviation of mean value over 20 maps as error bars for each model. We find that the initial redshift affects the convergence power spectra at a level of \( \sim 10\% \). It is important to note that the simulation from \( z_{\text{init}} = 49 \) is not set up consistently, because our simulation particles can represent only non-relativistic components, while the light gravitino is relativistic at such a high redshift. Overall, Figure 3 indicates that the simulated lensing power spectrum for the mixed dark matter model likely has inaccuracies with a level of \( \sim 10\% \).

5.2 Fisher analysis

We perform a Fisher analysis to forecast the cosmological parameter constraints, including \( m_{3/2} \). For a multivariate Gaussian likelihood, the Fisher matrix \( F_{ij} \) is written as

\[
F_{ij} = \frac{1}{2} \text{Tr} \left[ A_i A_j + C^{-1} M_{ij} \right],
\]

where \( A_i = C^{-1} \partial C / \partial p_i \), \( M_{ij} = 2 (\partial P_\kappa / \partial p_i)(\partial P_\kappa / \partial p_j) \), \( C \) is the data covariance matrix and \( p \) is a set of parameters of interest. \(^2\) In the present study, we choose \( p = (m_{3/2}, 10^9 A_s, n_s, \Omega_c h^2, \omega_b) \) as cosmological parameters to constrain. For the Fisher analysis, we need to calculate the derivative of \( P_\kappa \) with respect to \( p \). For \( m_{3/2} \), we first fit the measured power spectrum \( P_\kappa(\ell) \) using a quadratic form of \( m_{3/2} \), i.e. \( a_0(\ell) + a_1(\ell)m_{3/2} + a_2(\ell)m_{3/2}^2 \). We then calculate the derivative by \( a_1(\ell) + 2a_2(\ell)m_{3/2} \). For the other parameters, we evaluate the derivatives as follows:

\[
\frac{\partial P_\kappa(\ell)}{\partial p_i} = \frac{P_\kappa(\ell, p_i^{(0)}) + dp_i - P_\kappa(\ell, p_i^{(0)}) - dp_i}{2dp_i}.
\]

\(^2\)We only consider the second term in eq. (5.1). Because \( C \) scales approximately inverse-proportionally to survey area, the second term is expected to be dominant for a very wide area survey [54].
where \( p_{i}^{(0)} \) is the fiducial value and \( dp_{i} \) is the variation of \( i \)-th parameter. Here, we simply calculate \( P_{\kappa}(\ell, p) \) using eq. (4.8) and the fitting formula of \( P_{\delta}(k) \) in [49]. We summarize the fiducial values of \( p \) and \( dp \) in Table 3.

The covariance matrix of the convergence power spectrum can be expressed as a sum of the Gaussian and non-Gaussian contributions [45, 55]. Previous studies show that the non-Gaussian error degrades the constraints on cosmological parameters with a level of \( O(10\%) \) [56]. We calculate the non-Gaussian contribution by using 1000 lensing maps in [45] in the following direct manner:

\[
\text{Cov}[P_{\kappa}(\ell), P_{\kappa}(\ell')] = \frac{1}{N_{R} - 1} \sum_{r=1}^{N_{R}} (\hat{P}_{\kappa}^{r}(\ell) - \bar{P}_{\kappa}(\ell))(\hat{P}_{\kappa}^{r}(\ell') - \bar{P}_{\kappa}(\ell')), \tag{5.3}
\]

where \( \hat{P}_{\kappa}^{r}(\ell) \) is the measured power spectrum in \( r \)-th realization and \( \bar{P}_{\kappa}(\ell) \) is the average power spectrum over \( N_{R} = 1000 \) realizations. The configuration of the simulation in [45] is similar to ours, which covers 25 deg\(^2\) on the sky. When necessary, we simply scale the covariance matrix eq. (5.3) by the designated survey area.

We also take various systematic effects into account in the following manner. It is well-known that the intrinsic ellipticities of source galaxies induce noises to lensing power spectrum. Assuming intrinsic ellipticities are uncorrelated, we compute the noise contribution to the covariance matrix of convergence power spectrum as [57]

\[
\text{Cov}[P_{\kappa}(\ell), P_{\kappa}(\ell')]_{\text{noise}} = \frac{2}{f_{\text{sky}}(2\ell + 1)\Delta\ell}P_{\text{noise}} (P_{\text{noise}} + 2P_{\kappa}(\ell)) \delta_{\ell\ell'}, \tag{5.4}
\]

\[
P_{\text{noise}} = \frac{1}{n_{\text{gal}}} \left( \frac{\sigma_{\text{int}}}{\mathcal{R}} \right)^{2}, \tag{5.5}
\]

where \( \Delta\ell \) is the width of the multipole bin, \( f_{\text{sky}} \) is the fraction of sky covered, \( n_{\text{gal}} \) is the number density of source galaxies, \( \mathcal{R} \) is the shear response, and \( \sigma_{\text{int}} \) is the root-mean-square of the shear noise. Throughout the present paper, we adopt \( \mathcal{R} = 1.7 \) and \( \sigma_{\text{int}} = 0.4 \). The values are typical in ground based weak lensing surveys [58, 59]. We finally obtain the covariance matrix for our Fisher analysis as a sum of eq. (5.3) and (5.4). In Figure 4, we compare the derived statistical error (the square root of the diagonal part of the covariance matrix) and the estimated difference of the lensing power spectra between the mixed dark matter models considered here. Clearly, future wide field lensing surveys with 1500 square degrees can discriminate (or constrain) the light gravitino models. There are some certain degeneracies among the cosmological parameters, which we shall discuss in section 5.4.

### Table 3

Parameters in our Fisher analysis. For each parameter, we calculate the power spectra \( P_{\kappa} \) with \( dp \) varied around the fiducial value in order to calculate the derivative of Equation (5.2).

| Parameter | Value 1 | Value 2 | Value 3 | Value 4 | Value 5 |
|-----------|---------|---------|---------|---------|---------|
| \( m_{3/2} \) [eV] | 4.2 | 2.15 | 0.924 | 0.12029 | -1 |
| \( 10^{9} A_{s} \) | - | 0.1 | 0.01 | 0.03 | 0.1 |
| \( n_{s} \) | - | - | - | - | - |
| \( \Omega_{c} h^{2} \) | - | - | - | - | - |
| \( \omega_{0} \) | - | - | - | - | - |
We explore more realistic constraints by using priors expected from the cosmological parameter estimates from the Planck satellite mission. When we compute the Fisher matrix for the CMB, we use the Markov-Chain Monte-Carlo (MCMC) engine COSMOMC [60] for exploring cosmological parameter space. We consider the parameter constraints from the angular power spectra of temperature anisotropies, $E$-mode polarization, and their cross-correlation. For MCMC, in addition to $10^9 A_s, n_s, \Omega_c h^2$ and $w_0$, we adopt the baryon density $\Omega_b h^2$, Hubble parameter $h$, and reionization optical depth $\tau$ as independent parameters. To examine the potential of lensing power spectrum to constrain $m_{3/2}$, we do not assume any prior on $m_{3/2}$ from the CMB. Assuming that the constraints from the CMB and the lensing power spectrum are independent of each other, we express the total Fisher matrix as

$$F = F_{\text{lensing}} + F_{\text{CMB}}.$$  

(5.6)

When we include the CMB priors in this way, we marginalize over the other cosmological parameters except $p = (m_{3/2}, 10^9 A_s, n_s, \Omega_c h^2, w_0)$.

### 5.3 Forecast for future surveys

We provide the forecast for upcoming weak lensing surveys with an area coverage of more than a thousand square degrees. We use logarithmically spaced bins with $\Delta \log_{10} \ell = 0.1$ from $\ell = 100$ to 2000. We thus need a $14 \times 14$ covariance matrix of lensing power spectrum in the Fisher analysis. Our 1000 mock observations are sufficiently large to estimate the covariance matrix accurately.
Figure 5. We show the cosmological constraints from lensing power spectrum alone. We consider the upcoming Subaru Hyper Suprime-Cam survey with an area of 1500 deg$^2$.

Figure 5 shows the two-dimensional confidence contours for the Subaru Hyper Suprime-Cam (HSC) lensing survey. We assume $n_{gal} = 10$ arcmin$^{-2}$. The red circles show the constraints with 68% confidence level (1$\sigma$) whereas the blue ones correspond to 95% confidence level (2$\sigma$). The marginalized 1$\sigma$ error for $m_{3/2}$ over other parameters is found to be $\sim 18$ eV. Note that this is a constraint from the lensing survey alone. We also show the forecast with the CMB priors in Figure 6. The constraint on the gravitino mass is significantly improved in this case, because using the CMB data breaks some degeneracies among cosmological parameters, e.g. $10^9 A_s$ and $\Omega_c h^2$ [7]. It is impressive that we can derive constraint on the gravitino mass with a level of 1 eV by combining data from the HSC lensing survey and the Planck mission.

5.4 Degeneracy between massive neutrino

It is well known that massive neutrinos affect the lensing power spectrum in a similar way to the light gravitino; free-streaming of massive neutrinos suppress the growth of structure. At large length scales, the effect on $P_\delta(k)$ has been quantified by linear theory and extensions to first-order perturbation theory, e.g. [61, 62]. Probing the effect of massive neutrinos on $P_\delta(k)$ in the fully non-linear regime is still challenging, because it is difficult to include the relativistic species in $N$-body simulations [63–66]. In order to study the degeneracy between the light gravitino mass and the total mass of massive neutrinos in the cosmological parameter estimate, we utilize a fitting model of $P_\delta(k)$ that include the effect of neutrinos [66].

Figure 7 shows the effect of massive neutrinos on the lensing power spectrum. There, we assume the mass of neutrino $m_{\nu,\text{tot}} = 0.7$ eV, which is comparable to the current upper

\footnote{http://www.naoj.org/Projects/HSC/j_index.html}
limits with 95 percent confidence [67–69]. We compare the lensing power spectrum with those of the light gravitino with $m_{3/2} = 4$ and 16 eV. As expected, massive neutrinos with $m_{\nu,\text{tot}} = 0.7$ eV cause a similar effect on the lensing power spectrum to that of the light gravitino. It would thus be difficult to break the degeneracy between the contribution of the light gravitino and that of massive neutrinos by a weak lensing survey alone. We need other probes of the matter distribution at large scales and at different epochs, such as galaxy clustering. For example, future galaxy redshift surveys are aimed at measuring the galaxy clustering at $k \sim 0.01 - 0.1 \text{ h/Mpc}$. At the quasi-nonlinear scales, the effect of massive neutrinos on $P(k)$ can be distinguishable from that of the light gravitino, as shown in the right panel of Figure 7.

6 Summary and Discussion

The gravitino mass is one of the fundamental parameters in SUSY theory that is directly related to the SUSY breaking energy scale. We focus on the gauge-mediated supersymmetry breaking model that generically predicts the existence of light gravitinos with $m_{3/2} \sim \text{eV-keV}$. Free-streaming of such light gravitino affects the matter distribution significantly, leaving characteristic suppression in the matter power spectrum at around $k \gtrsim 0.1 \text{ h/Mpc}$. The nonlinear scale is beyond the reach of the CMB anisotropy measurements. We show that observations of weak gravitational lensing can be used to probe the matter distribution at the relevant length scales and thus can be used to detect the imprints of the light gravitino.

We have explored cosmological constraints on the light gravitino mass from cosmic shear statistics. Our ray-tracing simulations have revealed that the conventional model for nonlinear correction to the matter power spectrum [49] does not work well for models with the light gravitino. The difference between the simulation results and the fitting formula
Figure 7. The effect of the light gravitino and massive neutrinos on the lensing power spectrum (left) and on the three dimensional matter power spectrum at $z = 0$ (right). In each panel, the dashed line shows the resulting lensing power spectrum calculated by the fitting model in [66] including the effect of massive neutrinos. We assume $m_{\nu,\text{tot}} = 0.7$ eV. The points show the measured power spectra from our simulations in the case of $m_{3/2} = 4$ eV (red) and $m_{3/2} = 16$ eV (blue). We show these power spectra normalized by that for the pure CDM model.

is significant at $\ell \sim 1000$, where upcoming lensing surveys are aimed at measuring the power spectrum accurately. Using a large set of ray-tracing simulations, we have shown that the HSC like survey has a potential to determine the gravitino mass with an accuracy of $4 \pm 1$ eV with the help of Planck CMB priors on the basic cosmological parameters.

Let us further discuss prospects for future lensing surveys. For the upcoming survey with $20000$ deg$^2$ by the Large Synoptic Survey Telescope (LSST) $^4$, we will be able to use fainter galaxies for lensing analysis. Effectively the number of source galaxies will be larger. In this case, we can constrain on $m_{3/2}$ with a level of $4 \pm 0.6$ eV assuming $n_{\text{gal}} = 15$ arcmin$^{-2}$. Note that the constraint is tighter than the current one from the Lyman-$\alpha$ forest by a factor of $\sim 10$ $^2$, and also comparable to the forecast that utilizes CMB lensing $^3$. Although there is some certain degeneracy between the effect of massive neutrinos and that of the light gravitino in cosmic shear power spectrum, we argue that combining cosmic shear and galaxy clustering and/or CMB lensing can break the degeneracy. We summarize the forecast of $m_{3/2}$ from upcoming weak lensing survey in figure 8. There, we estimate the future constraint on the gravitino mass from the LHC 14 TeV run for the minimal GMSB model.

Ultimately, the International Linear Collider (ILC) experiment has a potential to determine the gravitino mass. When the next lightest supersymmetric particle is stau, its lifetime is proportional to the gravitino mass squared. By measuring the distribution of the impact parameter, one can evaluate the stau lifetime and hence the gravitino mass $^7$. $^5$ Overall, under reasonable assumptions, almost all of the interesting GMSB models with

---

$^4$http://www.lsst.org/lsst/

$^5$ To this end, the center of mass energy should exceed two time the stau mass and the background events should be effectively eliminated. However, this may be challenging for the present design of the ILC in the case of the heavy stau for a given gravitino mass, i.e. large $N_5$ and $\lambda x$. 

---
Figure 8. The likelihood distribution of \(m_{3/2}\) expected by future weak lensing surveys. We have used the binned lensing power spectrum with the CMB prior for this figure. The solid line corresponds to the Hyper Suprime-Cam survey and the dashed one for Large Synoptic Survey Telescope. The vertical lines show the current/future focus points of the GMSB model at the LHC (Table 1). In the near-future LHC, all GMSB models with \(m_{3/2} < 5\) eV (shaded region) can be probed if they involve the stable SUSY breaking (SB) vacuum and the successful grand unification.

\(m_{3/2} < 5\) eV can be probed in 15 fb\(^{-1}\) of LHC 14 TeV run. Combining cosmological and collider searches together, we will reach the conclusion about the GMSB model.

Acknowledgments

A.K. would like to thank M. Ibe, S. Matsumoto, and T. T. Yanagida for useful discussions. M.S. appreciates M. Sato for kindly providing us the set of simulations. Numerical computations for the present work have been carried out on Cray XC30 at Center for Computational Astrophysics, CfCA, of National Astronomical Observatory of Japan, and in part under the Interdisciplinary Computational Science Program in Center for Computational Sciences, University of Tsukuba. This work is supported in part by JSPS Research Fellowship for Young Scientists (A.K. and M.S.) and by World Premier International Research Center Initiative, MEXT, Japan.
