1. Introduction

Road traffic is one of the most dangerous types of human activity. The main causes of road accidents are driver fatigue, poor physical and mental condition of drivers and overestimating one's skills while driving. This study focuses on the estimation of driver response time, as the basis of a hypothetical system that uses short and long-range radars, which determines the physical and mental condition of a driver, based on the analysis of “acceleration noise” of the vehicle following its predecessor. This work highlights serious consequences of the fact that driver response time is described by means of a distribution with heavy tails, and thus may be a source of hazard in the driver-vehicle system. Extremes of driver response time were treated as outliers in this study.

Their detection was attained by using the Akaike information criterion [1, 2], which is an alternative to conventional methods of testing hypotheses. Unypical, on account of their outlying nature, values are interpreted as critical driver response time values which potentially endanger the reliability of driving.

Keywords: driver response time, reliability of road traffic, outliers, Akaike information criterion, log-normal distribution.

Ruch drogowy należy do najbardziej niebezpiecznych rodzajów działalności człowieka. Główne przyczyny wypadków drogowych to znęcenie kierowców, zły stan psychofizyczny kierujących oraz przecenianie swoich umiejętności podczas prowadzenia pojazdu. W niniejszej pracy skupiono uwagę na estymacji czasu reakcji kierowców, jako podstawie hipotetycznego systemu wykorzystującego radary dalekiego i krótkiego zasięgu a określającego stan psychofizyczny kierowcy w oparciu o analizę „szumu przyspieszeń” pojazdu podążającego za poprzednikiem. Wskazuje się na groźne konsekwencje faktu, że czas reakcji kierowcy jest opisywany rozkładem z ciężkimi ogonami, gdyż z tego powodu może być źródłem zagrożenia w układzie kierowca-pojazd. Skrajne wartości czasu reakcji kierowców potraktowano w pracy, jako wartości odstające. W ich wykrycia zastosowano kryterium informacyjne Akaike [1, 2] co stanowi alternatywę w stosunku do klasycznych metod testowania hipotez. Nietypowe, bo odstające wartości interpretuje się, jako krytyczne warości czasu reakcji kierowców potencjalnie zagrzajające niezawodności jazdy.

Słowa kluczowe: czas reakcji kierowców, niezawodność ruchu drogowego, obserwacje odstające, kryterium informacyjne Akaike, rozkład logarytmiczno-normalny.

1. Introduction

Road traffic is one of the most dangerous types of human activity. It is due to several factors, including the unreliability of the driver-vehicle system in the process of driving. According to WHO statistics, 1.2 million people die in car accidents each year. In the past 10 years on EU roads ca 0.5 million people were killed with over 1.5 million seriously injured and many people remain disabled for the rest of their lives. The annual cost of road accidents in the EU amounts to € 160 billion, which constitutes 2% of EU GDP. The risk of being a fatality on Polish domestic roads is four times greater than on roads in Germany and the UK, and on highways it is even six times greater.

In Poland, in 2005, as many as 57.3% of the accidents occurred on a straight stretch of road, and the most common cause of road accidents was excessive speed (28.8%), while failure to maintain a safe distance between vehicles causes 4.5% of accidents. In 2012, about 11% of accidents are the result of driving into the rear of another vehicle because of not maintaining a safe distance. The cause of up to one quarter of accidents on German highways is driver drowsiness. Most of these accidents have severe consequences. The main risk factors on roads are: human, as a participant of the traffic, the vehicle, and the road. As many as 90-95% of accidents are related to man and their behaviour. The vehicle contributes to causing 8-10% of road accidents, while the road and its surroundings contributes to 28-35% of road accident occurrence. These factors may impact the risk individually or several factors may combine (Fig. 1) [14, 20]. Archer [3] observed that at an average speed of 60 km/h average one risky situation for 120 km should be attributed to an average driver.

Human behaviour, ignorance of one’s own body, response to stress or the level of fatigue or excessive confidence in one’s own driving capability contribute to the occurrence of accidents. Other factors, such as weather conditions or the road surface condition, are much

2. System-based, on-going control of driver response time

Individual physiological characteristics define the limitations of the driver’s organism. Engineering psychology involves checking the following psycho-physical parameters of drivers: response time and its consistency, assessing vehicle speed, spatial vision, sensitivity of proprioception, sensitivity to glare and the ability to distinguish shapes in the darkness, speed and accuracy of perception, speed and accuracy of decision making, divisibility and concentration of attention, technical knowledge, resistance to fatigue, neuroticism [23]. The following are among the most important characteristics of a driver: quality of vision, response time and age.

Response time constitutes part of the time needed to stop a car. The manoeuvre of stopping a car before an appearing obstacle can be divided into the following: perception time, actual driver response time, time required to activate the braking system of the car and the actual braking time. In some publications perception time, which is the time elapsing between the moment the preceding vehicle brakes and the moment the central nervous system begins working, is included in the time slot called response time. Similarly, to this study, it stems from the conditions under which an experiment is conducted. The combined driver’s perception and response times may change, ranging from 1 to even a few seconds depending on:

- driver’s current health condition, mood, and physical characteristics (e.g. headache, being well-rested or tired),
- driver’s degree of concentration (long and monotonous drive or prolonged noise in the driver’s compartment can increase the response time by more than 10%),
- driver’s circadian rhythm (decreased vigilance, fatigue, drowsiness), time of year, day and meteorological phenomena (changes in atmospheric pressure and temperature of the environment, precipitation),
- ergonomic conditions (e.g. inappropriate placement of the control system elements, poorly adjusted parameters of the auxiliary subsystems),
- complexity of the traffic situation (surprise as a result of an unusual road situation), the number of options considered by the driver and the actual manoeuvres undertaken,
- street lighting, type of road (street, suburban road, motorway),
- insobriety, influence of psychotropics, intoxicating substances.

If the driver anticipates danger, it is assumed that the response time is 0.5-0.8 s. If the driver is careful but does not anticipate danger, it is 0.7-0.9 s. When the driver steers carelessly, it is 1.4-1.9 s. Computer reconstructions of road collisions often assume that the total perception and driver response time is 1.75 s. During night time this duration is longer and amounts to 2.5 s [5].

Response times estimated on the basis of laboratory test simulations ought to be taken very carefully. Most of these tests consist in measuring driver response time to a simple signal, i.e. such as measuring the time that elapses between the appearance of red light and pressing the brake pedal. These tests do not reflect the real conditions encountered by a driver in traffic and the measured response times are much shorter [35].

The constituent elements of the currently installed optional equipment of the vehicle, i.e. a combination of a stereoscopic camera with long and short range radar sensors, after appropriate reprogramming, allow for direct measurements of the response time of a driver following another vehicle. Multiple measurements of the time elapsing between the moment the preceding vehicle brakes and the moment of the following vehicle driver’s response can be a parameter that may be used in a variety of ways. It can, for example, be used to warn the driver about their poor psycho-physical condition, of the need to change their driving style or the parameters of auxiliary subsystems, it can also lead to reducing the speed of the vehicle, temporary exclusion from the traffic, signalling a problem to other users and even notifying the police about a threat.

3. Critical driver response time

In order to compare different traffic situations, Jones and Potts [21] proposed a probabilistic description of traffic flow, where a significant role was assigned to the parameter of \( \sigma_a - \) acceleration dispersion, commonly referred to as “acceleration noise” of a vehicle following its predecessor (the so-called dependent driving). Model testing has utilised this traffic quality indicator. Acceleration noise incorporates both the longitudinal and the transverse component. The latter is particularly visible on a winding road, but it has not yet been adequately examined [22]. Usually only the longitudinal component expressed by the following parameter is considered: \( \sigma_a - \) acceleration dispersion [4, 35]. The \( \sigma_a \) indicator was verified in simulation tests, and the results confirmed its correlation with statistical safety indicators. Effective research on real objects has not been yet conducted. The tragic death of the Polish precursor in real time traffic flow, Mieczysław Kaczmor, D.Eng., discontinued the already initiated research [23].

Acceleration dispersion is a consequence of the time of the driver’s response to the observed stimuli as well as their intensity, which are associated with the psycho-physical predispositions of the driver,
manifested in their driving style. Acceleration dispersion is also a performance function of the vehicles participating in road traffic.

"Acceleration noise" (sometimes referred to as "noise of accelerations") is the mean square deviation of the acceleration distribution of the vehicles participating in road traffic [13]. This indicator defines the inability to maintain a constant drive speed. If to determine the level of "acceleration noise" a measurement method called the "floating" vehicle is used, the "acceleration noise" of a traffic flow with a small error resulting from the limited time of T measurements can be determined by measuring changes in the tested vehicle acceleration. Then:

$$\sigma_a = \lim_{T \to \infty} T^{-1} \int_0^T \left[ a(t) - \bar{a} \right]^2 \, dt,$$

where \( a(t) \) – are respectively: realisations of the stochastic process \( X(t) \) (temporally random changes in the tested vehicle acceleration) and the average acceleration of the tested vehicle over the measuring distance \( [0, T] \).

The examination of the critical response time of drivers should allow us to show the relationship between potentially dangerous road traffic situations and the following categories of driver response time: typical and untypical, permissible and impermissible, safe and endangering safety. The assignment of any of these categories may refer to a single measurement, as well as a group of measurements. In the latter case, we will refer to the current characteristics of the physiological features of the driver, e.g. fatigue, intoxication. When the exemplary, typical individual characteristics of driver response time are known, they can be easily compared with characteristics of the current data stream, and then prevent a potential threat. Just like in systems monitoring driver fatigue by analysing the movements and fixation of the eyeball; they also deploy the comparison of the digital "rested eye" pattern with actual camera observations of the driver’s eye throughout the whole journey.

Each of these characteristics can be based on 1) the measurement of the percentage of stress exceeding a certain barrier or 2) filtering the data stream so that the highlighted group of multiple measurements will correspond to the actual probability of the response time distribution. By combining both methods, one can specify 3) the frequency parameter of the untypical driver response.

The system of managing the data stream coming from various sensors requires complex filtering and alarm activation in reaction to untypical observations [18]. In this study, the extreme values of driver reaction time are considered as the so-called "outlier measurements" values. While analysing the classical statistics of experimental results, it is important to determine whether the outliers are derived from a different population than the rest of the results. Then, in further analysis, untypical observations used to be customarily rejected. It is also possible, although unlikely to occur, that "strange" observations will emerge with the same distribution as for the remaining results. Then, it would be advisable to keep such observations for further statistical analysis, simultaneously increasing its effectiveness.

Methods of hypothesis testing are the most commonly used ones for the detection of outliers [6, 8, 15, 19, 30, 32]. However, conclusions in the hypothesis testing method are dependent on the assumed level of significance and may be different for its various values. Furthermore, there may appear the effect of outlier "masking". For the data on the strength of plastic materials, Grubb [19] describes a situation where tests do not detect one smallest observation, while two smallest observations are readily identified as outliers (a certain contradiction).

In this study, it is suggested to use the Akaike criterion information to detect outliers. This criterion, derived from information theory, allows one to select it from among the models describing experimen-
It is known that the maximum likelihood estimators of the log-normal distribution parameters are equal to [24]:

\[
\mu = \frac{1}{n} \sum_{i=1}^{n} \ln x_i, \quad \sigma^2 = \frac{1}{n} \sum_{i=1}^{n} \left( \ln x_i - \mu \right)^2.
\]  

(3)

Let us consider a sample of \( n \) observations, which, after arranging in an ascending order, form a sequence: \( x_{(1)} \leq x_{(2)} \leq \cdots \leq x_{(n)} \). Therefore, \( x_{(i)} \) denotes the value of the \( i \)-th positional statistics \( X_{i:n} \) from an \( n \)-element simple sample \( x \). The following notation have been adopted in the further part of this article:

\[
\Psi(x, \mu, \sigma^2) \quad \text{denotes the probability density function of distribution } \text{LN}(\mu, \sigma^2).
\]

\[
\Phi(x, \mu, \sigma^2) \quad \text{denotes the cumulative distribution function of } \text{LN}(\mu, \sigma^2).
\]

\[
f_{i:n}(x, \mu, \sigma^2) \quad \text{denotes the probability density function of the } i \text{-th positional statistics } X_{i:n}.
\]

Therefore, we have [11]:

\[
\Psi(x, \mu, \sigma^2) = \frac{1}{x\sigma\sqrt{2\pi}} \exp \left[ -\frac{(\ln x - \mu)^2}{2\sigma^2} \right], \quad x > 0 ,
\]  

(4)

\[
\Phi(x, \mu, \sigma^2) = \frac{1}{2} \left[ 1 + \text{erf} \left( \frac{\ln x - \mu}{\sigma\sqrt{2}} \right) \right], \quad x > 0 ,
\]  

(5)

\[
f_{i:n}(x, \mu, \sigma^2) = [B(i, n-i+1)]^{-1} \left[ \Phi(x, \mu, \sigma^2) \right]^{i-1} \left[ 1 - \Phi(x, \mu, \sigma^2) \right]^{n-i} \Psi(x, \mu, \sigma^2),
\]  

(6)

where \text{erf} is a special function (non-elementary) called the Gauss error function, \( B(p, q) \) denotes the beta special function:

\[
B(p, q) = \int_{0}^{1} t^{p-1}(1-t)^{q-1} dt, \quad p > 0 , \quad q > 0 .
\]  

(7)

It is known that:

\[
B(p, q) = \frac{\Gamma(p)\Gamma(q)}{\Gamma(p+q)} = \frac{(p-1)!(q-1)!}{(p+q-1)!}
\]  

for natural \( p \) and \( q \), while \( \Gamma(x) \) denotes the Euler’s gamma special function.

Denoting \( EX = \mu^* \), \( VAR(X) = (\sigma^*)^2 \) one can observe in the Table 1 that both \( \mu^* \) and \( (\sigma^*)^2 \) depend on \( \mu, \sigma^2 \) parameters and vice versa. Therefore, all the functions \( \Phi, \Psi \) and \( f_{i:n} \) are dependent on \( \mu^* \) and \( (\sigma^*)^2 \).

5. Model of outliers

Consider the following situation: an ordered \( n \)-element sample is given:

\[
X_{(1)} \leq X_{(2)} \leq \ldots \leq X_{(n)} \quad \text{and} \quad X_{(n-1)} \leq \ldots \leq X_{(n-n_0)} \leq X_{(n-n_0+1)} \leq \ldots \leq X_{(n)}
\]

\( n \) of the lowest observations
\( n-n_0 \) of the highest ones

from the log-normal distribution. The ‘main part’ of the sample group is derived from a population with an average of \( \mu^* \), and the outliers may constitute the lowest observations group or the highest observations group. They originate from populations of different \( \mu^*_1 \) and \( \mu^*_2 \) average values. Detection of outliers is generally performed using the procedure of hypothesis testing at a certain level of significance. Then, relevant hypotheses have the following form:

\[
H_0: \quad \text{outliers, that is } \mu^*_1 = \mu^*_2 ,
\]

\[
H_{1A}: \quad \text{there exist lowest outliers, that is } \mu^*_1 < \mu^*,
\]

\[
H_{1B}: \quad \text{highest outliers, that is } \mu^*_1 < \mu^*_2 ,
\]

\[
H_{1C}: \quad \text{there exist lowest and highest outliers, that is } \mu^*_1 < \mu^* < \mu^*_2 .
\]

Here outliers are determined using the Akaike information criterion. Thus, by setting the parameters accordingly: \( \mu^*_1 < \mu^* < \mu^*_2 \) and the same \( \sigma^* \) for all groups of observation, we obtain:

\[
\mu^*_1 < \mu < \mu^*_2 \quad \text{and} \quad \sigma^*_1 < \sigma^* < \sigma^*_2 .
\]  

(10)

Therefore, the model with outliers can be described in the following way:

\[
h(x_{(i)}) = \begin{cases} 
\Psi(X_{(i)}), & \text{for } i = 1, \ldots, n_1 \\
\sum_{i=n_1+1}^{n_1+n_2} f_{i:n}(x_{(i)}, \mu^*_1, \sigma^*_1) & \text{for } i = n_1 + 1, \ldots, n_2 - 1 \\
\Psi(X_{(i)}), & \text{for } i = n - n_2 + 1, \ldots, n 
\end{cases}
\]

6. Akaike information criterion

In order to determine the value of the Akaike information criterion (1) for the model (11) we find its likelihood function:

\[
\ln L(n_1, n_2, \mu, \mu_1, \mu_2, \sigma_1, \sigma_2 | x) = \frac{n_1}{2}\ln \sigma_1^2 - \frac{1}{\sigma_1^2} \sum_{i=n_1+1}^{n} \ln \Phi(x_{(i)}), \ln \Psi(x_{(i)}), \ln \sigma_1^2
\]

Thus, in view of (4), (5) and (6) the logarithm of the likelihood function equals to:

\[
\ln L(n_1, n_2, \mu, \mu_1, \mu_2, \sigma_1, \sigma_2 | x) = -n \ln (2\pi\sigma) + \frac{1}{2\sigma^2} \sum_{i=1}^{n} \ln (\ln x_i - \mu)^2
\]

\[
+ \frac{1}{2\sigma^2} \ln \prod_{i=n_1+1}^{n} \left[ \Phi(x_{(i)}), \ln (\ln x_{(i)} - \mu_1)^2 \right] + \frac{1}{2\sigma^2} \ln \prod_{i=n_1+n_2+1}^{n} \left[ 1 - \Phi(x_{(i)}), \ln (\ln x_{(i)} - \mu_2)^2 \right]
\]

(12)

that is:

\[
\ln L(n_1, n_2, \mu, \mu_1, \mu_2, \sigma_1, \sigma_2 | x) = -\frac{1}{2} \sum_{i=1}^{n} \ln (2\pi\sigma^2) + \frac{1}{2\sigma^2} \sum_{i=1}^{n} \ln (\ln x_i - \mu)^2
\]

(13)
where \( j = i - n_1 \), \( k = n - n_1 - n_2 \) and:

\[
\mu^t = \begin{cases} 
\mu_1 & \text{if } 1 \leq i \leq n_1 \\
\mu & \text{if } n_1 < i \leq n - n_2 \\
\mu_2 & \text{if } n - n_2 < i \leq n
\end{cases}
\]

(14)

Finally, for the observed sample \( x \) the value of the Akaike information criterion function \( AIC(n_1, n_2) \) dependent on \( n_1 \) and \( n_2 \) equals:

\[
AIC(n_1, n_2) = -2(n_1, n_2, \mu, \sigma^2) x + 2 - 2 \text{ if } n_1 = 0, n_2 = 0
\]

\[
-2(n_1, n_2, \mu, \hat{\mu}_1, \hat{\sigma}^2) x + 2.3 \text{ if } n_1 \neq 0, n_2 = 0
\]

\[
-2(n_1, n_2, \mu, \hat{\mu}_1, \hat{\mu}_2, \hat{\sigma}^2) x + 2.4 \text{ if } n_1 \neq 0, n_2 \neq 0
\]

(15)

where \( \hat{\mu}, \hat{\mu}_1, \hat{\mu}_2 \) and \( \sigma^2 \) denote estimators of model parameters obtained with the maximum likelihood method.

### 7. Experimental research

Experimental research was conducted at the Institute of Transportation Systems and Electrical Engineering of the University of Technology and Humanities in Radom. Driver response times were recorded at a fixed intensity level of real road traffic and fixed biometeorological conditions using a device allowing for measurements in both stationary and dynamic conditions. The device received a signal by radio from the preceding vehicle, in which a transmitter activated by pressing the brake pedal was installed. The voltage powering the brake lights switched on the signal in the measurement impulse transmitter, installed in the vehicle following with the test driver. This device measured the number of measurement impulses and converted this number into time, with the accuracy of 10⁻² s. Pressing the brake pedal by the test driver resulted in stopping the time measuring device and saving the driver response time with the above-mentioned accuracy. At the same time the situation on the road was filmed through the windshield [23].

### 8. Results

An example of a representative measurement result stream of the response time obtained from one of the drivers is illustrated in the histogram (Fig. 2). It appears that the driver response time has a log-normal distribution. This is confirmed by the shape of the histogram, and the results of statistical tests (Table 2). The values of all the tests: Kolmogorov-Smirnov, Cramer-von Mises and Anderson-Darling, presented in the third column of Table 2, clearly indicate that there are no grounds to reject the hypothesis of the log-normal distribution of driver response time. The calculations of tests values and drawings were performed with the SAS version 9.3 program. Using the theory developed in the previous chapters, the values of the Akaike information criterion \( AIC \) for various configurations of outliers (different numbers of the lowest and highest outliers) were found. The results are presented in Table 3.

As presented in Table 3, the lowest value of the Akaike information criterion \( AIC \), marked with an asterisk, indicates that in the studied stream the outlying response times are the ones from the set containing two lowest and six highest values. Highlighted in Figure 3 are the times significantly deviating from a straight line which, using a logarithmic scale, corresponds to the regression line \( y = 8.056 \cdot \exp(0.0306 \cdot t) \) for \( n_1 < i \leq n - n_2 \) which provides characteristics of the psycho-physical condition of the analysed driver within the studied period. After rejecting extreme observations, the values in 2 out of 3 tests checking the fitting of data stream to the log-normal distribution in Table 2,
9. Conclusions

The probability function $R(t) = 1 - F(t) = P(T \geq t)$ conventionally known as the reliability function (reliability function) or survival function, on account of the pejorative nature of the long $T$ time of the driver’s response, should rather be termed as the “risk function” here. Due to the fact that for $t = 0$ value $R(0) = 1$ and $\lim_{t \to \infty} R(t) = 0$, the “risk function” is a non-growing function of $t$ time and it expresses the probability of the right-hand “tail” distribution. That is to say, the “risk function” refers to the description of probability for the extreme values being the most adverse to the safety of road traffic. Therefore, attention should be paid to the rate of convergence of the right tail to 0. In systems described by normal distributions, the occurrence of extreme events (from tails) is so low that, in practice, such events are not observed. It is expressed by the three-sigma rule. While a single long driver response time constitutes a major threat to road safety. Hence, the statement that the driver response time in real traffic has a log-normal distribution means that the distribution of the driver response time has a heavy right-hand tail, i.e. the response times can reach relatively high values with significant probabilities. Therefore, the identification of driver response time in real traffic as a variable having a large right-hand tail of a log-normal distribution shows it to be a major risk source in road traffic. And then the observation made in the representative Fig. 3, whereby the six highest outliers from the right-hand tail significantly exceed the values of the already heavy right-hand tail, additionally compounds the horror of dangerous situations. Moreover, the downward deviation of the two shortest response times from the typical time distribution presented in Fig. 3, points to the driver’s nervous reactions. These results may also indicate loss (deterioration of) driving smoothness, and this is correlated with a risk increase, and consequently with the risk of traffic accident occurrence. Therefore, the additional identification of both groups of critical driver response times with a heavy right-hand tail of their distribution combines to indicate the existence of three potential threats to the reliability of the driver-vehicle system on the part of the driver, resulting in the deterioration of road safety. Thus, it is necessary to seek systems of driver support which are aimed at eliminating these threats.
