ABSTRACT

Context. High-resolution spectroscopy is a powerful tool to study the dynamical structure of pulsating stars.

Aims. We aim at comparing the line asymmetry and velocity of the two δ Scuti stars ρ Pup and DX Cet with previous spectroscopic data obtained on classical Cepheids and β Cep stars.

Methods. We obtained, analysed and discuss HARPS high-resolution spectra of ρ Pup and DX Cet. We derived the same physical quantities as used in previous studies, which are the first-moment radial velocities and the bi-Gaussian spectral line asymmetries.

Results. The identification of $f = 7.098 \text{ d}^{-1}$ as a fundamental radial mode and the very accurate Hipparcos parallax promote ρ Pup as the best standard candle to test the period-luminosity relations of δ Scuti stars. The action of small-amplitude nonradial modes can be seen as well-defined cycle-to-cycle variations in the radial velocity measurements of ρ Pup. Using the spectral-line asymmetry method, we also found the centre-of-mass velocities of ρ Pup and DX Cet, $V_r = 47.49 \pm 0.07 \text{ km s}^{-1}$ and $V_r = 25.75 \pm 0.06 \text{ km s}^{-1}$, respectively. By comparing our results with previous HARPS observations of classical Cepheids and β Cep stars, we confirm the linear relationship between the atmospheric velocity gradient and the amplitude of the radial velocity curve, but only for amplitudes larger than 22.5 km s$^{-1}$. For lower values of the velocity amplitude (i.e., $< 22.5 \text{ km s}^{-1}$), our data on ρ Pup seem to indicate that the velocity gradient is null, but this result needs to be confirmed with additional data. We derived the Baade-Wesselink projection factor $p = 1.36 \pm 0.02$ for ρ Pup and $p = 1.39 \pm 0.02$ for DX Cet. We successfully extended the period-projection factor relation from classical Cepheids to δ Scuti stars.

1. Introduction

The variability of ρ Pup = HD 67523 = HR 3185, one of the brightest $(V = 2.88)$ δ Scuti stars, was first reported by Cousins (1950) and then clearly demonstrated by Eggen (1956) and Ponsen (1963). An accurate value of the pulsational period $(P = 0.14088143 \text{ d})$ was determined from photometric data spanning fifty-two years (Moon & van Antwerpen 2009). Atmospheric parameters (effective temperature, surface gravity, and metallicity) were determined from ELODIE spectra by using the MILES library interpolator (Prugniel et al. 2011): $T_{\text{eff}} = 6810 \pm 121 \text{ K}$, log $g = 3.59 \pm 0.14$, and [Fe/H] = $+0.60 \pm 0.05$. The [Fe/H] value confirms that ρ Pup is a member of the δ Del subgroup, that is, late-A and early-F subgiants showing spectra with enhanced metal-lines (especially the Fe I, Y II, Fe II and Zr II ones) and normal H and Ca II lines (Kurtz 1976, and references therein).

ρ Pup is a well-known case where the determinations of the atmospheric parameters by means of Strömgren photometry $(b-y = 0.259, m_1 = 0.215, c_1 = 0.731, \beta = 2.715)$ disagree in function of the photometric indices used in the calibrations. This could be ascribed to its particular metallic content. Indeed, the spectroscopic values agree excellently with those obtained from $b - y$ and $c_1$ indices, that is, 6850 K and log $g = 3.5$ (Breger 1974; Kurtz 1976). Pioneering IUE spectra show emission features in the Mg II lines throughout the pulsation cycle (Fracassini et al. 1983). Later, detailed spectroscopic investigations of the pulsation properties were performed by Mathias et al. (1997) and Dall & Frandsen (2002). Very recently, the results of a dedicated spectroscopic multisite campaign excluded solar-like oscillations with an amplitude per radial mode larger than 0.5 m s$^{-1}$ (Antoci et al. 2013).

DX Cet = HD 16189 is a bright high-amplitude δ Scuti (HADS) star with a period $P = 0.103939529 \text{ d}$ and full amplitude of 0.20 mag in $V$ light (Kiss et al. 1999). Stellar parameters were obtained from $uvby$β photometry (Kiss et al. 1999; Stetson 1991): $T_{\text{eff}} = 7250 \pm 200 \text{ K}$, log $g = 3.6 \pm 0.2$ dex.

Comparing the spectroscopic analysis of these two δ Scuti stars (ρ Pup and DX Cet) with previous results obtained on classical Cepheids and β Cep stars is extremely interesting for various reasons. First, for a given pulsating star, and also when comparing one star to the other, the spectral lines asymmetry show a systematic difference in average (over one pulsation cycle) that is positive or negative, depending on the spectral line considered. This effect is related to the dynamical structure of the star’s atmosphere and has been investigated in the case of classical Cepheids by means of the k-term (Nardetto et al. 2008, 2009).
Since the physical origin of this phenomenon is currently not under- 
stood, the comparison of the results obtained for several types of 
pulsating stars is particularly helpful. Second, Nardetto et al. 
(2013) found a linear relation between the atmospheric velocity 
gradient and the amplitude of the radial velocity curve for 
eight classical Cepheids and two β Cep stars (α Lup and τ1 Lup). 
This relation is important in the context of the Baade-Wesselink 
projection factor (Nardetto et al. 2004, 2007), a quantity that is 
used to derive the distance to Milky Way and Large Magellanic 
Cloud Cepheids (Storm et al. 2011). Improving this relation and 
generalizing it to other pulsators like δ Sct stars is an interest- 
ing roadmap to better understand the Baade-Wesselink projec- 
tion factor. Finally, the use of pulsating stars located below 
the horizontal branch as distance indicators requires the mode 
identification as input parameter, and often this is a challeng- 
ing task to achieve (Poretti et al. 2008). Therefore, the full char- 
acterization of bright, short-period δ Sct stars is a key matter in 
calibrating their period-luminosity (P-L) relation.

In Sect. 2 we briefly present our spectroscopic data. In 
Sect. 3 we analyse the pulsating frequencies of the two δ Sct stars. 
In Sect. 4 we discuss the implication of our data on the 
derived distances and on the P-L relations. Sect. 5 is then de- 
voted to the spectroscopic analysis of the two targets in terms of 
spectral line asymmetry and velocity. In Sect. 6 we compare our 
results on δ Sct stars with those on classical Cepheids and β Cep 
stars. We close with some conclusions in Sect. 7.

2. Spectroscopic observations and physical 
parameters

We observed ρ Pup and DX Cet as additional targets in the 
framework of the ESO LP185-D-0056. The observations were 
planned to extend the physical scenario of the δ Sct stars ob- 
served with CoRoT.

Three-hundred fifty-nine spectra of ρ Pup were ob- 
tained with High-Accuracy Radial-velocity Planetary Searcher 
(HARPS; Mayor et al. 2003) in the high-resolution mode 
(HAM, R = 115,000) on five consecutive nights in January 2013. 
Observations were performed for a few hours at the end of night, 
as a backup program. The exposure time was set at 30 sec and the 
signal-to-noise ratio (S/N) was typically about 270. Figure 1 (left panel) shows the behaviour of the mean line profile of each spec- 
trum folded with the pulsational period. Forty-three spectra of 
DX Cet were obtained with HARPS in the high-efficiency mode 
(EGGS, R = 80,000) on nine consecutive nights in December 2012. 
Observations were performed for a few hours at the begin- 
ing of night, before the rising of CoRoT targets. The exposure 
time was set at 300 sec and the S/N was usually around 200 (see Fig. 1 right panel). The radial velocity values of ρ Pup were 
obtained from the HARPS pipeline (Mayor et al. 2003), while 
those of DX Cet were obtained from the mean line profiles of 
each spectrum, calculated using the least-squares deconvolution method (Donati et al. 1997).

We estimated the physical parameters of both stars by means of 
a grid of synthetic spectra. For this purpose we selected four 
HARPS spectra with a high S/N that were taken at intervals of a 
quarter of a period starting from the maximum of the radial ve- 
locity curve. To save computing time, we reconstructed the syn- 
thetic spectra in five 200 Å segments in the range 4000-6650 Å by 
using the ATLAS9 models and the ATC code (Atmospheric 
Tools Compilation; Stuetz et al. 2006). Temperature, gravity, 
metallicity, and microturbulence velocity were allowed to vary 
in the range 6400 ≤ Teff ≤ 8000 K, 2.6 ≤ log g ≤ 4.8 dex 
(cgs units), −1.0 ≤ [Fe/H] ≤ 1.0, and 0 ≤ vmic ≤ 6 km s−1, re- 
spectively. We compared the synthetic 200 Å-segments with the 
observed ones by computing the χ2. At the end of this process, 
each segment supplied a set of physical parameters obtained by 
averaging its own best 50 least-squares solutions. In turn, these 
five sets were averaged to give the physical parameters at the pulsa- 
tion phase of the HARPS spectrum that we were considering. 
Then, the averages of the four Teff, log g, [Fe/H], and vmic values 
corresponding to the four pulsation phases supplied the mean 
stellar parameters. The typical uncertainties of the parameters 
 supplied by one spectrum were also adopted as the errorbars of 
the mean stellar parameters.

The procedure described above supplied T eff = 6650 ± 100 K, 
 log g = 3.42 ± 0.14 dex, [Fe/H] = +0.20 ± 0.06, and vmic = 4.2 ± 0.7 km s−1 for ρ Pup. Moreover, we measured a projected 
rotational velocity veq sin i = 13 ± 1 km s−1. In the case of DX Cet 
we obtained T eff = 7200 ± 100 K, log g = 3.58 ± 0.14 dex, 
vmic = 3.4 ± 0.4 km s−1, [Fe/H] = −0.27 ± 0.06, and veq sin i = 7 ± 1 km s−1. Therefore, our spectroscopic analyses yields out 
that DX Cet has a slight subsolar metallic content, while ρ Pup 
is confirmed to be a metal-rich star.

To support the [Fe/H] determination of DX Cet in view of 
the discussion of the P-L relations (see Sect. 4), Fig. 2 shows the 
agreement between the observed spectrum and the synthetic 
ones calculated with the above parameters.

Hipparchos parallaxes are available for both stars 
(van Leeuwen 2007): π = 8.65 ± 0.80 mas for DX Cet and 
π = 51.33 ± 0.15 mas for ρ Pup. DX Cet is located at 
116±5 pc and we obtain M V = 1.68±0.20 assuming V = 7.00. 
ρ Pup is much closer, at 19.48±0.03 pc only, and we derive 
M V = 1.36±0.01 from the well-established V = 2.81 magnitude. 
In the case of ρ Pup, the parallax immediately supplied 
L = 24.0 ± 0.2 L⊙. Combined with the interferometric de- 
termination of the radius (R = 3.52 ± 0.07 R⊙; Antoci et al. 
2013), this implies T eff = 6820 ± 170 K, in good agreement 
with our spectroscopic value. Furthermore, we introduced T eff, 
P, Q=0.033 d (corresponding to the fundamental radial mode), 
Mw, and the bolometric correction +0.03 mag (Torres 2010) in 
the relation (Breger & Bregman 1975)

log Q = −6.456 + log P + 0.5 log g + 0.1 Mbol + log T eff ,

thus obtaining log g=3.70±0.02. This latter value agrees within 
2σ with ours (log g=3.42±0.14) and within 1σ with that of 
Prugniel et al. (2011) (log g=3.59±0.14). When applying the 
same approach to DX Cet, Eq. 2 can only supply the condition 
log g + 2.0 log T eff = 11.56(±0.04),

(2)

since we have no radius measurement (see also Poretti et al. 2011). Our spectroscopic values match this condition at about 
1σ (11.53±0.16). Since in the case of ρ Pup the T eff value is 
well constrained, this comparison shows that the log g determina- 
tion is the most critical parameter to evaluate.

3. Frequency analyses and nature of pulsations

3.1. ρ Pup

An exhaustive list of photometric measurements of ρ Pup was 
reported by Moon & van Antwerpen (2009), Ponsen (1963), 
Eggen (1956), and Hipphearcos (ESA 1997). The data are the most 
suitable for a detailed analysis. Data were obtained in different 
passbands: Ponsen’s measurements were taken through a blue 
filter, Eggen’s through a yellow filter, and those of Hipphearcos.
Table 1. Least-squares parameters of the HARPS radial velocity curves of ρ Pup (T0=BJD 2456293.0056) and DX Cet (T0=BJD 2456272.5889).

| ID | Frequency [d^{-1}] | Amplitude [km s^{-1}] | Phase [0, 2π] | ID | Frequency [d^{-1}] | Amplitude [km s^{-1}] | Phase [0, 2π] |
|----|---------------------|------------------------|--------------|----|---------------------|------------------------|--------------|

Mean rad. vel. [km s^{-1}] 46.739±0.002
Residual r.m.s. [km s^{-1}] 0.041

Fig. 1. Mean profiles of ρ Pup (left panel) and DX Cet (right panel) observed during different nights and folded with the respective pulsation period. Spectral intensities (in continuum units) on the y-axis are arbitrarily shifted to clearly show the profile variations.

Fig. 2. Fitting of the FeI lines in the spectrum of DX Cet. The HARPS spectrum (black solid line) is compared with the synthetic spectrum obtained with $T_{\text{eff}} = 7100$ K, log $g = 3.55$ dex, $v_{\text{mic}} = 3.4$ km s^{-1}, and [Fe/H]=-0.27 (red dashed). Intensities are normalized to the continuum level.

in the wide $H_{\alpha}$ passband. The folded light curves show asymmetric shapes (Fig. 1). The full amplitudes are 0.13, 0.11, and 0.09 mag, respectively. These values fit the sequence observed at 3858, 4310, 4720, and, 5875 Å, that is, 0.17, 0.14, 0.12, and 0.09 mag (Thulassi Doss 1969). Amplitude ratios ($R_{21}$) and phase shifts ($\phi_{21}$) were obtained from a least-squares fit with $f = 1/P$ and $2f (P=0.14088143$ d): $\phi_{21} = 3.85 \pm 0.12$ rad and $R_{21} = 0.05 \pm 0.01$ for Ponsen’s blue data, $\phi_{21} = 4.26 \pm 0.22$ rad and $R_{21} = 0.14 \pm 0.03$ for Eggen’s yellow data, and $\phi_{21} = 4.19 \pm 0.10$ rad and $R_{21} = 0.09 \pm 0.01$ for Hipparcos data. Taking into account the different passbands, these Fourier parameters agree excellently and suggest significant departure from a perfect sine-shaped light curve. The Fourier parameters of ρ Pup light curves are typical for HADS stars (Figs. 4 and 6 in Poretti 2001). These stars pulsate in a radial mode (typically the fundamental one) and nonradial modes have a much smaller amplitude. However, the amplitude of ρ Pup is not so large that it could be considered as that of a bona-fide HADS star, and more analyses are necessary.

The multiperiodicity of ρ Pup was evident after the detection of clear cycle-to-cycle variations in the radial velocity values obtained with the Coudé Echelle Spectrograph (CES) at the CAT ESO telescope (Mathias et al. 1997). The main oscillation $f_1 = 7.098168$ d^{-1} was identified as a radial mode and two
nonradial modes with frequency 7.8 and 6.3 d\(^{-1}\) were also proposed, but the latter is very uncertain. We used the iterative sine–wave least–squares fitting method [Vaniček 1971] to analyse in frequency the radial velocity measurements obtained from the HARPS spectra, determined by the on-line pipeline with an internal error of about 1 m s\(^{-1}\). After the detection of \(f_1\), the power spectrum clearly shows a structure centred at 2\(f_1\), confirming that the radial velocity curve is asymmetrical, as well. The folded radial velocity curve shows both the asymmetrical shape and cycle-to-cycle variations up to 0.36 km s\(^{-1}\) (Fig. 4). Asymmetry can be evaluated from the maximum, which occurs at phase 0.0, while the minimum occurs before phase 0.50 (black filled circles). After introducing \(f_1\) and 2\(f_1\) as known constituents, the highest peak in the power spectrum of HARPS data is at \(f_2=7.900\) d\(^{-1}\), in good agreement with the value obtained from CAT data (i.e., 7.815 d\(^{-1}\). [Mathias et al. 1997]). However, we note that the spectral windows of both datasets are not adequate to perform a very detailed, self-consistent frequency analysis, since these spectroscopic data were acquired with the goal of studying the dynamics of the dominant pulsation mode. The ground-based photometric data are too noisy to supply useful hints about \(f_2\). Even Hipparcos data are unsuitable to search for a small amplitude, short-period additional mode. However, the spectral window of these data is free from the \(\pm 1\) d\(^{-1}\) aliasing, and we could see, among many others, a peak at 8.860 d\(^{-1}\). [Antoci et al. 2013] pointed out 8.82 d\(^{-1}\) as a possible additional frequency. Therefore, we calculated the least-squares fit by considering \(f_2=8.860\) d\(^{-1}\), but the residual r.m.s. (0.067 km s\(^{-1}\)) is poorer than that obtained using \(f_2=7.900\) d\(^{-1}\) (0.041 km s\(^{-1}\)). An additional analysis of new data (e.g., Antoci et al. 2013, in preparation) may be able to ascertain the true value. We adopted \(f_2=7.900\) d\(^{-1}\) to describe the dynamical structure of \(\rho\) Pup, and the effect of this choice is evaluated at the end of Sect. 5.1.

Table 1 lists the least-squares solution obtained from the HARPS data. The mean value of the radial velocity, 46.74 km s\(^{-1}\), and the 2\(K\) value (peak-to-peak amplitude of the radial velocity curve), 9.9 km s\(^{-1}\), agree both excellently with all the literature values. The former suggests that \(\rho\) Pup is a single star, the latter that the pulsation is very stable over decades (see also [Moon & van Antwerpen 2009]). The power spectrum of the residuals shows other modes excited around \(f_1\), but the poor spectral window does not allow us to confirm the values proposed by [Antoci et al. 2013]. In the other parts of the residual power spectrum we were able to observe not only the bunches of peaks related to the higher harmonics of \(f_1\), but also those related to the combination terms between \(f_1\) (and harmonics) and the additional modes. As stressed by [Antoci et al. 2013], these patterns affect the same region in which solar-like oscillations are expected to leave their fingerprints. All these unresolved components contribute to increase the residual r.m.s. of the solution.

Neither our radial velocity curve nor Ponsen’s photometry (blue light should be sensitive to this effect) show the bump provoked by a shock wave crossing the atmosphere [Dravins et al. 1977]. The emission features in the Mg II lines and the radial velocity curves in the ultraviolet do not show any particular behaviour either [Fracassini et al. 1983]. In the top panel of Fig. 4 cycle-to-cycle variations can be noticed especially at the minimum, which seems to occur at different phases. This strange behaviour is only apparent because \(\rho\) Pup was observed more at the minimum than at the maximum. For sake of clarity, we investigated the possibility of transient or particular events in the atmosphere dynamics around maximum compression and subsequent expansion. A close examination of the core of the Ca II K line did not reveal any emission during the observations. Therefore, the cycle-to-cycle variations in radial velocity data are definitely unrelated to the variations in the chromospheric activity.

**Fig. 3.** Light curves of \(\rho\) Pup. **Top panel:** [Eggen 1956] data, 60 measurements from 19 to 26 March, 1956. **Middle panel:** [Ponsen 1963] data, 658 measurements from January 30 to April 23, 1961. **Bottom panel:** Hipparcos data [ESA 1997], 248 measurements from January 4, 1990 to February 24, 1993.

**Fig. 4.** **Top panel:** HARPS radial velocity values of \(\rho\) Pup. Different symbols (colours) denote different nights. Cycle-to-cycle variations are clearly visible around the minimum. **Bottom panel:** HARPS radial velocity values of DX Cet. The solid line is the fit with \(f_1\) and three harmonics (Table 1).
3.2. DX Cet

The solution of the radial velocity curve of DX Cet is much simpler than that of ρ Pup. The five components $f_1=9.6197 \text{ d}^{-1}$, $2f_1$, $3f_1$, $4f_1$, and $5f_1$ are detected in the power spectrum and provide a very satisfactory fit of the radial velocity curve (Table 1 and Fig. 3). The fit of the Hipparcos data (ESA 1997) supplied the Fourier parameters $R_{01}=0.24 \pm 0.02$, $\phi_{01}=3.9 \pm 0.1$, and $\phi_{01}=1.4 \pm 0.4$ rad. They are typical values for HADS stars (Fig. 4, 5, and 6 in Poretti et al. 2001). The mean $H\pi$ magnitude is $7.077 \pm 0.005$, which in turn yields $V=7.00$ for $B_V-V_T=0.33$ (Bessell 2003). This value and the full amplitude of 0.21 mag as well agree with those reported by Kiss et al. (1999). The 2$K$/d$=23.1$ s$^{-1}$ value supports radial pulsation.

4. ρ Pup and DX Cet as distance indicators

The Hipparcos parallaxes and the identification of the pulsation modes of ρ Pup and DX Cet as the fundamental radial ones allowed us to test the P-L relations of HADS stars. There are two P-L relations:

$$M_V = -1.83(0.08) - 3.65(0.07) \log P$$

(Poretti et al. 2008), and

$$M_V = -1.27(0.05) - 2.90(0.07) \log P - 0.19(0.015)[\text{Fe/H}]$$

(McNamara 2011). Eq. [3] was obtained by using all the short-period ($P<0.20$ d) stars that pulsate in the fundamental radial mode and are located in a wide variety of stellar systems. It provides an excellent fit without knowing any other parameter than the period. The metal-dependent term was introduced in Eq. [4] with the goal to determine the same law for HADS and Cepheids and should only be considered when [Fe/H]$<0.0$ (McNamara 2011).

For DX Cet, Eq. [3] supplies $M_V = 1.76 \pm 0.10$ and Eq. [4] $M_V = 1.64 \pm 0.07$ for [Fe/H]$=-0.27$. Both predictions agree excellently with the Hipparcos $M_V$, and hence $P=0.104$ d can definitely be identified as the fundamental radial mode. For instance, by assuming that the pulsation is in the first overtone mode, the corresponding fundamental mode would be 0.135 d, and the P-L relations would predict $M_V=1.3$, which does match the Hipparcos $M_V$. Due to the relevant error on the parallax, McNamara (2011) applied an LK correction (~0.10 mag, then $M_V=1.58 \pm 0.20$) (Lutz & Kelker 1973), but the star becomes too bright to fit the value predicted by Eq. [4] in a more satisfactory way.

However, because it is a statistical procedure, the LK correction is powerful when applied to a sample of stars (with same π) and is much more uncertain when applied to a single case (e.g., Oudmaijer et al. 1998).

The period of ρ Pup is among the longest in the 3.2 Scp sample. Eqs [3] and Eq. [4] predict similar values without the metal-dependent term, that is, $M_V = 1.28 \pm 0.10$ and $M_V = 1.21 \pm 0.07$, respectively. The former agrees excellently with the very accurate $Hipparcos M_V = 1.36 \pm 0.01$ value, while the latter is slightly outside error bars. We note that using of the [Fe/H] correction in Eq. [4] shifts the calculated value too far ($M_V = 1.09 \pm 0.07$) from the observed one. Therefore, this correction definitely does not have to be applied to stars when [Fe/H] $> 0.0$. Moreover, assuming that $f_1$ is the first radial overtone, we derive $M_V=0.87$ from the P-L relations, a too bright luminosity for the Hipparcos parallax. This convinced us that ρ Pup is pulsating in the fundamental radial mode.

This achievement adds an important stellar candle to the sample of galactic δ Scp stars with known parallaxes. The current inventory is composed of nine stars (Table 2 in McNamara 2011). However, the identification of the fundamental radial mode is very reliable only for high-amplitude pulsation, that is, the HADS stars DX Cet, ε Vel, and SX Phe. One can add δ Scp itself, since detailed investigations (Templeton et al. 1997) corrected the previous identification of the dominant mode as a radial overtone (Balona et al. 1981). The remaining five cases are rather uncertain, starting with 1 Mon, whose dominant mode has been identified as an overtone (Balona & Stobie 1980). It is instructive to note that the dominant modes of FG Vir and X Cae are nonradial (Zima et al. 2006; Mantegazza et al. 2000): the fundamental radial mode, if it is indeed excited, has to be searched for in the low-amplitude terms, with a wide margin of uncertainty. α Aql (Altair) is a fast rotating star and the nature of the very weak amplitude variations (<0.001 mag) detected with the WIRE satellite can be generated by a wide variety of modes. In particular, there is no convincing evidence that the observed modes are radial ones (Suárez et al. 2005). Finally, no mode identification has been proposed for the small-amplitude variations (0.02 mag) observed for BS Tuc. Therefore, ρ Pup is by far the most convincing case of a δ Scp pulsating in the fundamental radial mode with an accurate Hipparcos parallax.

5. Spectroscopic analysis

We performed a detailed analysis of the high-S/N HARPS spectra of ρ Pup and DX Cet following the procedure described in Nardetto et al. (2006a). We selected 45 spectral lines, taking care that they were not blended.

We extracted radial velocity and line asymmetry curves for all selected lines of all stars. The method we use for the radial velocity (that is the best one to use when the signal-to-noise ratio allows it) is the first moment of the spectral line, $RV_c$. The radial velocity curve derived from this method is absolutely independent of the spectral line width and the rotation. This property is extremely valuable for comparing the behaviour of different spectral lines of different pulsating stars. We also derived the spectral line asymmetries $A$ with a very high precision, using an estimator that we call the bi-Gaussian: two analytic semi-Gaussians are fitted to the blue and red part of the spectral line profile. The amount of asymmetry (in percentage) is then given by the comparison of the half-width at half-maximum of each semi-Gaussian (see Nardetto et al. 2006a, their Eqs. 2 and 3). This definition was well-suited to the data quality. The period of ρ Pup is among the longest in the 3.2 Scp sample. Eqs [3] and Eq. [4] predict similar values without the metal-dependent term, that is, $M_V = 1.28 \pm 0.10$ and $M_V = 1.21 \pm 0.07$, respectively. The former agrees excellently with the very accurate $Hipparcos M_V = 1.36 \pm 0.01$ value, while the latter is slightly outside error bars. We note that using of the [Fe/H] correction in Eq. [4] shifts the calculated value too far ($M_V = 1.09 \pm 0.07$) from the observed one. Therefore, this correction definitely does not have to be applied to stars when [Fe/H] $> 0.0$. Moreover, assuming that $f_1$ is the first radial overtone, we derive $M_V=0.87$ from the P-L relations, a too bright luminosity for the Hipparcos parallax. This convinced us that ρ Pup is pulsating in the fundamental radial mode.

This achievement adds an important stellar candle to the sample of galactic δ Scp stars with known parallaxes. The current inventory is composed of nine stars (Table 2 in McNamara 2011). However, the identification of the fundamental radial mode is very reliable only for high-amplitude pulsation, that is, the HADS stars DX Cet, ε Vel, and SX Phe. One can add δ Scp itself, since detailed investigations (Templeton et al. 1997) corrected the previous identification of the dominant mode as a radial overtone (Balona et al. 1981). The remaining five cases are rather uncertain, starting with 1 Mon, whose dominant mode has been identified as an overtone (Balona & Stobie 1980). It is instructive to note that the dominant modes of FG Vir and X Cae are nonradial (Zima et al. 2006; Mantegazza et al. 2000): the fundamental radial mode, if it is indeed excited, has to be searched for in the low-amplitude terms, with a wide margin of uncertainty. α Aql (Altair) is a fast rotating star and the nature of the very weak amplitude variations (<0.001 mag) detected with the WIRE satellite can be generated by a wide variety of modes. In particular, there is no convincing evidence that the observed modes are radial ones (Suárez et al. 2005). Finally, no mode identification has been proposed for the small-amplitude variations (0.02 mag) observed for BS Tuc. Therefore, ρ Pup is by far the most convincing case of a δ Scp pulsating in the fundamental radial mode with an accurate Hipparcos parallax.
5.1. \( \rho \) Pup

We performed a least-squares fit of the observed values of \( RV_c \) and \( A \) by means of the Fourier series

\[
y(t) = B_0 + \sum_{i=1}^{5} B_i \cos((t - T_0) f_i + \phi_i) \tag{5}
\]

and by using \( f_1 = 7.098 \text{d}^{-1}, f_2 = 7.900 \text{d}^{-1}, f_3 = 2 f_1, f_4 = 3 f_1, \) and \( f_5 = 4 f_1 \). In this way we were able to fold the data on one mode by subtracting the contribution of the other. Figure 5 shows the folded points with \( f_1 \) of the radial velocities (panel a) and asymmetries (panel b) for the three following lines, CH 4634.07 (blue), FeI 5410.91 (green), and FeI 6393.60 Å (red), respectively. The corresponding averages of these curves (or similarly \( B_0 \) values obtained from Eq. 5) are shown as horizontal lines in panels a and b (in dash-dotted, dashed and solid lines), and are called \( \gamma \)-velocities and \( \gamma \)-asymmetries. The residual systematic scatter is caused by the contamination from very small amplitude modes that are still not identified after \( f_1 \) and \( f_2 \). There is an evident anticorrelation: higher velocities correspond to negative asymmetries, low velocities to positive asymmetries. This behaviour is also shown by the trend in the harycenters (big crosses of the \( RV_c - A \) loops (Fig. 5 panel c). By plotting for each line the \( \gamma \)-velocity and the \( \gamma \)-asymmetry, we can calculate the parameters of the analytic relation

\[
V_i(t) = a_0 A_i(t) + \beta_0, \tag{6}
\]

thus obtaining \( a_0 = -0.12 \pm 0.01 \text{ km s}^{-1} \) and \( \beta_0 = 47.49 \pm 0.07 \text{ km s}^{-1} \) (Fig 5 panel d). Following Nardetto et al. (2008), the centre-of-mass velocity of the star is defined as \( V_r = \beta_0 = 47.49 \pm 0.07 \text{ km s}^{-1} \) (i.e., the \( \gamma \)-velocity corresponding to a null \( \gamma \)-asymmetry). We note that the contributions of \( f_2 = 7.900 \text{ d}^{-1} \) to the \( \gamma \)-velocity and \( \gamma \)-asymmetry are much less important than those of \( f_1 \), which means that they affect the spectral line asymmetries in a marginal way. The k-term, defined as \( k = \Delta V_r \), \( \Delta V_r = 47.0_{-0.1}^{+0.1} - 47.5_{-0.1}^{+0.1} = -0.5 \pm 0.1 \text{ km s}^{-1} \), where \( \Delta V_r \) is the \( \gamma \)-velocity averaged over the 45 spectral lines. We briefly discuss the k-term problem in Sect. 5.3.

The next step of the spectroscopic analysis is to measure the velocity gradient within the atmosphere of the star. In Nardetto et al. (2007), we have shown that the line depth (taken at the minimum radius phase) is a good indicator of the line-forming regions. We use this definition of the line depth (hereafter \( D \)) in the following. In this case, the photosphere corresponds to a null line depth. By comparing the 2K amplitude (defined as the amplitude of the first-moment radial velocity curve, hereafter \( \Delta RV_c \)) with the depth of the 45 spectral lines selected, one can in principle directly measure the atmospheric velocity gradient (at least in the part of the atmosphere where the lines form). For \( \rho \) Pup, we found the following relation (see also Fig. 6).

\[
\Delta RV_c = (0.95 \pm 0.49)D + [8.84 \pm 0.19] \text{ km s}^{-1}. \tag{7}
\]

This relation (in which we define the slope and the zero-point by \( a_0 \) and \( b_0 \), respectively) can be used to derive the Baade-Wesselink projection factor following the semi-theoretical approach presented in Guiglion et al. (2013). The projection factor is used to convert the radial velocity into the pulsation velocity in the Baade-Wesselink methods of distance determination. It is composed of three terms: \( p = p_{0} \gamma \) (Nardetto et al. 2007). First, the geometric projection factor, \( p_{0} \), is mainly related to the limb-darkening of the star. The linear limb-darkening

---

**Fig. 5.** Illustration of the method applied to derive the centre-of-mass velocity of \( \rho \) Pup from the line asymmetries. Points are single observations folded with \( f_1 = 7.098 \text{ d}^{-1} \); the contribution from \( f_2 = 7.900 \text{ d}^{-1} \) has been removed.

**Fig. 6.** Amplitude of the \( RV_c \) curves as a function of the spectral line depth in the case of the two \( \delta \) Sct stars \( \rho \) Pup (lower values) and DX Cet (larger values). In the case of \( \rho \) Pup, red solid line show the same relation but after removing the nonradial mode.
law of the continuum intensity profile of the star provided by Claret & Bloemen (2011) is 
\[ I(\cos(\theta)) = 1 - \mu_R + \mu_R \cos(\theta), \]
where \( \mu_R \) is the limb darkening of the star in \( R \) band and \( \theta \) is the angle between the normal of the star and the line of sight. For \( \rho \) Pup we found \( \mu_R = 0.484 \) (considering the rounded values \( T_{\text{eff}} = 6500 \text{K}, \log g = 3.5, \nu_{\text{mic}} = 4 \text{ km s}^{-1} \), and \( Z = 0.0 \)). Using the relation linking \( \rho_0 \) to \( \mu_R \): \( \rho_0 = \frac{1}{3} - \frac{2}{3} \) (Getting 1934) [Hadrava et al. 2009], we found \( \rho_0 = 1.416 \). In this determination of the geometric projection factor, we assumed (as done previously for Cepheids) that the limb-darkening variation within the lines [Nardetto et al. 2007] and that the geometric projection factor time-dependency in the \( R \) band [Nardetto et al. 2006b] are negligible.

Then, \( f_{\text{grad}} \) depends on the spectral line considered: 
\[ f_{\text{grad}} = b_0/\left( a_0 D + b_0 \right) \] (Nardetto et al. 2007, their Eq. 3). For \( \rho \) Pup, it ranges from 0.94 (\( D = 0.22 \)) to 0.98 (\( D = 0.55 \)). For a typical depth in our sample of \( D = 0.4 \), we find \( f_{\text{grad}} = 0.96 \pm 0.01 \). Finally, there is a linear relation between \( f_{\text{grad}} \) (correction to the projection factor due to the differential velocity between the optical and gas layers at the photosphere of the star) and \( \log \rho_{\text{eff}} \): 
\[ f_{\text{grad}} = -0.023 \pm 0.005 \log \rho_{\text{eff}} + 0.979 \pm 0.005 \] (derived using classical Cepheids; Nardetto et al. 2007). When we apply this relation for \( \rho \) Pup as in Guiglion et al. 2013 for the \( \delta \) Sct stars AI Vel and \( \beta \) Cas, we found \( f_{\text{grad}} = 1.00 \pm 0.02 \). The final value of the projection factor of \( \rho \) Pup is thus \( \rho = \rho_0 f_{\text{grad}} \) \( \rho_{\text{eff}} = 1.36 \pm 0.02 \).

From a methodological point of view, it is interesting to note that we find \( a_0 = 0.88 \pm 0.49 \) and \( b_0 = 8.56 \pm 0.19 \) (i.e., a decrease of the slope and zero-point of the relation by 8% and 3%, respectively) when fitting the original data with \( f_1 \) and harmonics alone. In turn, this increases the value of \( f_{\text{grad}} \), and consequently that of \( \rho \), by only 0.2%. In a similar way, there is no change in the parameters of Eq. 4 and a non-significant decrease of the zero-point of Eq. 5 (from 8.86 to 8.84 km s\(^{-1}\)) when using \( f_2 = 8.86 \text{ d}^{-1} \) instead of 7.90 d\(^{-1}\) (see Sect. 5.1).

5.2. DX Cet

We applied the same analysis to DX Cet. Figure 2 (panels a and b) shows the radial velocity and line asymmetry curves for the three lines FeI 4213.65, FeI 5393.17, and FeI 6393.60 Å. We found the same anticorrelation between the \( \gamma \)-velocity and the \( \gamma \)-asymmetry:

\[ V_\gamma(i) = [-0.15 \pm 0.03] \gamma_\star(i) + [25.75 \pm 0.06]. \]

The centre-of-mass velocity of the star is then \( V_\gamma \star = \beta_0 = 25.75 \pm 0.06 \text{ km s}^{-1} \) and the k-term is \( k = -V_\gamma > -V_\gamma \star = 25.75 \pm 0.1 \text{ km s}^{-1} \).

For the atmospheric velocity gradient we found (Fig. 6)

\[ \Delta V_\gamma = [1.15 \pm 0.48] D + [21.62 \pm 0.14] \text{ km s}^{-1}, \]

which corresponds to a velocity gradient or \( f_{\text{grad}} \) correction of the projection factor ranging from 0.97 (\( D = 0.12 \)) to 0.99 (\( D = 0.49 \)). The average value \( f_{\text{grad}} = 0.98 \pm 0.01 \) (\( D = 0.30 \)) was used. From the rounded values available in Claret & Bloemen (2011), \( T_{\text{eff}} = 7000 \text{ K}, \log g = 3.5, \nu_{\text{mic}} = 2.0 \text{ km s}^{-1} \), and \( Z = -0.3 \), we obtained \( \mu_R = 0.474 \) and a geometric projection factor \( \rho_0 = 1.421 \). Considering, as for \( \rho \) Pup, \( f_{\text{grad}} = 1.00 \pm 0.02 \), we finally found a Baade-Wesselink projection factor \( \rho = 1.39 \pm 0.02 \) for DX Cet.

Fig. 7. Same as Fig. 5 for DX Cet.

6. Comparing \( \delta \) Scuti stars with \( \beta \) Cep stars and classical Cepheids

Our HARPS sample is composed of stars with a good phase coverage and for which we were able to measure the spectral line asymmetry properly. We have eight classical Cepheids (R TrA, S Cru, Y Sgr, \( \epsilon \) Gem, \( \beta \) Dor, RR Vel, \( \tau \) Car, and RS Pup; Nardetto et al. 2008), two \( \delta \) Sct stars (\( \rho \) Pup and DX Cet; this paper), and the \( \beta \) Cep star \( \alpha \) Lup (Nardetto et al. 2013). Moreover, we have other cases. AI Vel has an incomplete phase coverage that prevented us from measuring the \( \gamma \)-asymmetry, although we were able to measure the atmospheric velocity gradient and the projection factor. \( \beta \) Cas is rotating too fast to measure the spectral line asymmetry or derive the atmospheric velocity gradient with a good precision. Thus, we determined the projection factor only with a large uncertainty (Guiglion et al. 2013). The classical Cepheid X Sgr shows spectral line splitting due probably to a shockwave in the atmosphere (Mathias et al. 2006). The \( \beta \) Cep \( \tau \) Lup shows significant nonradial modes (Nardetto et al. 2013) and we were unable to consistently apply the bi-Gaussian method to measure the line asymmetry.

In Fig. 8 we compare \( V_\gamma(i) = \alpha_0 A_\gamma(i) + \beta_0 \) relations between the \( \gamma \)-velocities and the \( \gamma \)-asymmetries (after correcting for the zero-point) found for \( \rho \) Pup and DX Cet, with previous results obtained for the \( \beta \) Cep star \( \alpha \) Lup and for the eight classical Cepheids mentioned above. It is remarkable that the results obtained for \( \delta \) Scuti stars and classical Cepheids are consistent, while \( \alpha \) Lup shows a different behaviour (steeper slope of the relation). We also note that \( \alpha \) Lup has only negative \( \gamma \)-asymmetries (at least over the 55 spectral lines considered in Nardetto et al. 2013). It is currently very difficult to interpret this behaviour, but at least qualitatively, we can conclude that there is a particular physical mechanism that probably affects the \( \alpha \) Lup spectral lines asymmetry, while this is not the case for the \( \delta \) Scuti and Cepheid stars.

For the k-term quantity, we found \( k = -0.5 \text{ km s}^{-1} \) and \( k = 0 \text{ km s}^{-1} \) for \( \rho \) Pup and DX Cet, respectively. These values are
Fig. 8. Same as Figs. 5 and 7, but including the results obtained for classical Cepheids (averaged over eight stars) and α Lup (β Cep star). The horizontal lines at the bottom show the corresponding γ-asymmetry ranges.

Fig. 9. Velocity gradient in the atmosphere of the stars as a function of the amplitude of the RV curves.

consistent with those found for Cepheids (values ranging from 0 to $-1$ km s$^{-1}$ depending on the period of the star, Nardetto et al. 2013). By using a Cepheid in an eclipsing binary system ($P_{\text{puls}} = 3.8$ d, $P_{\text{orb}} = 309$ d), Pilecki et al. (2013) independently found a blue-shifted value $k = -0.59$ km s$^{-1}$. On the other hand, α Lup shows a red-shifted value $k = 2.2$ km s$^{-1}$.

Fig. 10. The Baade-Wesselink projection factor as a function of the period for different kinds of pulsating stars. The δ Scuti stars indicated as blue diamonds are, by increasing period: β Cas, DX Cet, AI Vel and ρ Pup.

Figure 9 shows the slope $a_0$ (from the $\Delta RV_c = a_0 D + b_0$ relation) as a function of the 2K-amplitude (i.e., $b_0$). The results obtained for δ Scuti stars, β Cep stars, and classical Cepheids are compared. The case of τ$^1$ Lup must be considered separately, as previously mentioned in Nardetto et al. (2013). This star indeed shows a reverse atmospheric velocity gradient, which means that a line forming in the upper part of the atmosphere has a 2K-velocity amplitude lower than a line forming closer to the photosphere. This might be because of the nonradial mode detected in the spectroscopic data. On the other hand, ρ Pup has a null velocity gradient for a similar velocity amplitude of about $b_0 \approx 10$ km s$^{-1}$. It has to be confirmed, but it seems that stars with a dominant radial mode and with $b_0$ lower than 22.5 km s$^{-1}$ have a null atmospheric velocity gradient (dashed line in the figure). Conversely, we can convincingly consider a linear trend (solid line in the figure) for 2K-amplitudes larger than 22.5 km s$^{-1}$:

$$a_0 = [0.29 \pm 0.04] b_0 - [6.61 \pm 1.36].$$

The comparison of the projection factors within our sample is also very interesting. In the framework of our project, we determined the Baade-Wesselink projection factor for four δ Sct stars: ρ Pup ($p = 1.36 \pm 0.02$), DX Cet ($p = 1.39 \pm 0.02$), AI Vel ($p = 1.44 \pm 0.05$), and β Cas ($p = 1.41 \pm 0.25$). Figure 10 shows that all these values excellently fit the extension toward short periods of the relation found for Cepheids, that is, $p = [-0.08 \pm 0.05] \log P + [1.31 \pm 0.06]$ (Nardetto et al. 2009). This result seems more robust than the similar one obtained by Laney & Joner (2005), who used an indirect method based on the comparison of geometric and pulsation parallaxes. On the other hand, the projection factor of the β Cep star α Lup is 8σ higher than the relation (Fig. 10). By omitting α Lup, we can determine the following relation common to δ Sct stars and classical Cepheids:

$$p = [-0.08 \pm 0.01] \log P + [1.31 \pm 0.01],$$

(9)
which is similar to the one derived for Cepheids only, but more precise (the reduced $\chi^2$ is 0.97).

However, we have to stress some methodological points. First, in the projection factor decomposition ($p = p_0 f_{\text{grad}} f_{\text{rot}}$), the third component, $f_{\text{rot}}$, was extrapolated for the $\delta$ Scuti stars (not for $\alpha$ Lup, for which we used a dedicated hydrodynamical model), while the $f_{\text{grad}}$ quantity was derived directly and independently from observations. We also recall that the geometric projection factor, $p_0$, is directly linked to the limb-darkening and thus to the fundamental parameters of the stars. Second, for the Cepheids, the projection factors are consistent with the cross-correlation method of the radial velocity determination. For DX Cet and $\rho$ Pup, the line depth considered for the $f_{\text{grad}}$ correction is typical (i.e., averaged over all lines considered in our sample), which means that the derived projection factors are in principle very close to those to be used in the cross-correlation method. For $\alpha$ Lup, AI Vel, and $\beta$ Cas, there is no velocity gradient in the atmosphere and the projection factor is the same regardless of the line considered, and thus is consistent with the cross-correlation method. There remains only the fact that in the cross-correlation method a Gaussian is fitted to the cross-correlated spectral line profile, which in principle reduces the value of the projection factor by few percents compared with that based on the first-moment method ([Nardetto et al. 2006a]).

Reducing the projection factor for short pulsators in Fig. 10 by a few percents will basically not change the relative position of $\alpha$ Lup and our qualitative conclusion that the period-projection factor relation seems to straightly link $\delta$ Scuti stars and classical Cepheids. Third, the fast rotation of some $\delta$ Scuti stars (as well as the inclination of their rotation axis) can affect the projection factor by 10% or even more ([Guiglion et al. 2013]). However, the $\delta$ Scuti stars in our sample show $v_{\text{rot}} \sin i$ values lower than 13 km s$^{-1}$, except for $\beta$ Cas with $v_{\text{rot}} \sin i \approx 75$ km s$^{-1}$.

Even if we were able to derive both the Baade-Wesselink projection factors and the centre-of-mass velocities for the eleven pulsating stars in our sample, an effort (both observational and theoretical) has still to be made to understand the spectral line asymmetry properly. For classical Cepheids, the hydrodynamical models reproduce the observed velocities and even the atmospheric velocity gradient very well ([Fokin 1994, Nardetto et al. 2004, 2007]). Nevertheless, currently, there is no hydrodynamical model of pulsating stars that can correctly reproduce the $\gamma$-velocities and $\gamma$-asymmetries. In particular, we emphasize that the $k$-term quantity cannot be explained by a Van Hoof effect ([Mathias et al. 1993, 1995]). In Fig 11 we show the Van Hoof diagram for the three spectral lines of Sect. 5.1 for $\rho$ Pup.

The Van Hoof effect is not detected because there is no phase shift between the radial velocities of the different spectral lines (i.e., no loops). We also find that the two curves have a slope close to one, indicating a null atmospheric velocity gradient, as already mentioned. Nevertheless, the zero-points of the two curves are shifted, as a result from the $\gamma$-velocity offsets (Fig. 5 panel a). The possible physical causes of these offsets (e.g., additional modes) are under analysis.

### 7. Conclusions

We presented HARPS high-resolution spectra of $\rho$ Pup and DX Cet, thus increasing our sample to eleven stars. Among them, the $\beta$ Cep star $\alpha$ Lup shows an interesting positive value of 2.2 km s$^{-1}$ for the $k$-term, while other kinds of pulsating stars have negative values (ranging from $-1$ to $0$ km s$^{-1}$). We also found that $\rho$ Pup shows the same 2K velocity amplitude (8.84 $\pm$ 0.19 km s$^{-1}$) regardless of the spectral line considered in our sample (45 lines), while this is not the case for stars with amplitudes larger than 22.5 km s$^{-1}$, where a trend is indeed found as a function of the the line depth. This behaviour, if confirmed, would mean that the atmospheric velocity gradient correction on the Baade-Wesselink projection factor, $f_{\text{grad}}$, is equal to 1.0 for any type of pulsating star as soon as its 2K velocity amplitude is lower than 22.5 km s$^{-1}$. Finally, we found that the period-projection factor relation might be common to classical Cepheids and $\delta$ Scuti, while the $\beta$ Cep star $\alpha$ Lup stands at 8$\sigma$ above the relation.

The excitation of different pulsation modes (fundamental and overtone radial, pressure and gravity nonradial) usually makes the use of $\delta$ Scf stars as distance indicators problematic. For $\rho$ Pup, our analysis of light and radial velocity curves identified the dominant mode as the fundamental radial one. Because it is a very bright star with an accurate *Hipparcos* parallax, $\rho$ Pup can be now considered as the best standard candle for the $\delta$ Sct class. The *Hipparcos* absolute magnitude gives us a luminosity log $L/L_\odot$=1.38. Combined with $T_{\text{eff}}$=6650-6800 K, this implies that $\rho$ Pup is very close to the red border of the instability strip, probably leaving the central part where most of the HADS stars are located ([Pamyatnykh 2000]).

Moreover, from the *Hipparcos* parallax ($\pi$ = 7.02 $\pm$ 0.17 mas), the mean radius of $R = 3.52 \pm 0.07 R_\odot$ ([Antoci et al. 2013]), and our value of the projection factor $p = 1.36$ together with our radial velocity curve (in particular, 2K = 8.8 km s$^{-1}$), we were able to infer an absolute angular diameter variation of 11 $\mu$as (or 0.7%). Unfortunately, there are no K photometric observations of $\rho$ Pup that cover a full pulsation cycle to which one might apply the infrared surface brightness relation and confirm these findings.

![Fig. 11. Van Hoof diagram for $\rho$ Pup. The radial velocity curve associated to the FeI 5410.91 (green) and FeI 6393.60 Å (red) spectral line profiles is plotted as a function of the same quantity, but for CrI 4634.07. The solid line corresponds to the identity function. There is no Van Hoof effect detected (no loops), while the $\gamma$-velocity effect is clearly seen (y-axis offsets of the curves).](image-url)
