Abstract

Background

Corona virus disease (COVID-19) originated in China in December 2019. Thereafter, a global logarithmic expansion of the cases has occurred. Some countries have a higher rate of infections despite of early implementation of quarantine. Air pollution could be related to the high susceptibility to SARS-CoV-2 and the associated case-fatality rates (deaths/cases*100). Lima, Peru has the second highest incidence of COVID-19 in Latin America and it is also one of the cities with highest levels of air pollution in the Region.

Methods

This study investigated the association of the levels of PM$_{2.5}$ exposure in the previous years (2010–2016) in 24 districts of Lima with the cases, deaths and case-fatality rates of COVID-19.

Results

Until June 12, 2020, there were 6,308 deaths and 220,749 SARS-CoV-2 positive cases in Peru. In Lima, the total number of COVID-19 deaths in all metropolitan areas was 2,382. The case-fatality rate at the national level was 2.58% and 1.93% in Lima. Higher PM$_{2.5}$ levels are associated with higher number of cases and deaths of COVID-19. The case-fatality rate (Deaths/cases*100) did not increase with the increase in PM$_{2.5}$ levels. A higher number of food markets was associated with higher incidence and mortality of COVID-19 ($p<0.01$ for both); these associations persisted when cases ($r = 0.49; p<0.01$) and deaths ($r = 0.58; p<0.01$) were adjusted by the population density. The association of PM$_{2.5}$ with cases of COVID-19 was maintained after controlling analysis by age, sex and number of food markers.

Conclusions

The higher rates of COVID-19 in Metropolitan Lima is attributable, among others, to the increased PM$_{2.5}$ exposure in the previous years after adjusting for age, sex and number of food markets. Reduction of air pollution since a long term perspective, and social distancing are needed to prevent spreads of virus outbreak.

Introduction

Corona virus disease (COVID-19) is caused by the severe acute respiratory syndrome corona virus 2 (SARS-CoV-2) and was first reported in December 2019 from Wuhan in the Hubei province of the Republic of China [1]. On March 11, 2020, due to the global logarithmic expansion of the cases, COVID-19 was declared a pandemic by the World Health Organization (WHO) [2]. On March 6, 2020, the Peruvian
president had announced the first COVID-19 infection case in Lima – an imported case of a Peruvian national who returned from recent travel to France, Spain, and the Czech Republic [3]. On March 11, 2020, the President declared a general quarantine with social distancing interventions, including closures of all educational institutions (i.e., schools and universities) in Peru, and on March 16, 2020, a national emergency was declared [3].

Three months after the declaration of the emergency and strict measures of social isolation, the rates of infection are extremely high in the Lima metropolitan area than in the rest of the country. As of June 12, 2020, there were 128,700 (58.3%) COVID-19 cases in Lima and 92,049 (41.7%) in the rest of the country. Several reasons have been suggested to explain the high incidence of COVID-19 and the inability to reduce the scaling up of the COVID-19 outbreak.

A similar situation with a high incidence of the outbreak in one specific region of a country that is different from that in other regions has been described in Italy. In Italy, the highest incidence of COVID-19 has been observed in the northern part of the country [,4,5].

Several studies have explored the association between SARS-CoV-2 transmission and the COVID-19 mortality rate with environmental factors, air pollution being among them [6, 7]. In New York, which is the epicenter of the COVID-19 epidemic in the United States, it was observed that short-term exposure to ozone and other meteorological factors can influence SARS-CoV-2 transmission and susceptibility to infection, but was not associated with disease exacerbation and mortality, which seem to be dependent on other factors [7].

One explanation of the higher rate of SARS-CoV-2 infection is that the susceptibility of the population to the virus is predetermined by the exposure to air pollutants in the previous years. A higher rate of infection with COVID-19 in northern Italy was apparently related to the highest levels of air pollution in that part of the country [8]. It is suspected that individuals with chronic PM$_{2.5}$ exposure suffer progressive and chronic inflammation of the respiratory tract and are more prone to severe respiratory diseases after viral infections [4].

Lima is one of the most polluted cities in Latin America [9], and it is possible that long-term exposure to air pollutants may increase the infection susceptibility of individuals to different external agents, including bacteria and viruses [10–12]. In the city of Lima, PM$_{2.5}$ concentrations vary by seasonality based on meteorological conditions. In late autumn and winter (lower temperatures), the gas–particle conversion processes increase the environmental PM$_{2.5}$ concentrations [13]. Another possibility is that the virus could be loaded onto the particulate matter (PM), which then acts as a vector for infection spread, extending the persistence of the viral particles in the air, thereby favoring an “indirect” transmission in addition to the direct spread (individual to individual) [5].

Based on these arguments, it has been suggested that a reduction in the air pollution that occurred secondary to the shutting down of national and international transportation could reduce the disease spread [14,15] and thus may explain the decreased incidence of COVID-19.
The experience in Peru seems to demonstrate that the reduction in air pollution was unassociated with reduction of COVID-19 cases. The daily PM$_{2.5}$ concentrations showed a gradual decrease from March 16 and did not exceed the environmental quality standards for air that were specified by the Peruvian Ministry of the Environment. On average, for Lima, a 38% decrease for PM$_{2.5}$ was recorded (during the first 15 days of the state of emergency) compared to its historical concentrations (2015–2019) [16]. However, in the same period the cases of COVID-19 in Lima increased much more than in the rest of the country, representing 58% of the cases from all the country.

Unlike other governments worldwide, the Government of Peru declared quarantine as soon as the first case was detected. After the declaration of the emergency, the level of air pollutants was greatly reduced although new cases of COVID-19 continued increasing.

We hypothesized that air pollution could have a chronic effect that increases the susceptibility of individuals to the virus and that individuals living in places with high air pollution in the years preceding the pandemic are at a higher risk of infection.

To evaluate this hypothesis, this study involved the analysis of data from 24 districts of Lima that are characterized by different levels of PM$_{2.5}$ exposure in the years preceding the COVID-19 outbreak to evaluate whether the values obtained in previous years were associated with the incidence and mortality rates of COVID-19.

The primary objective was to determine if long-term exposure with different PM2.5 concentrations was associated with the number of cases, death and case-fatality rates to COVID-19. Then, we will to determine if this association is modified by age, sex, and number of food markets per district.

**Material And Methods**

This research was undertaken as an ecological study that involved the analysis of two secondary databases. We assessed the data of COVID-19 cases and deaths that occurred in Lima metropolitan area until June 12, 2020. We comparatively analyzed the data on COVID-19 with the estimate daily levels of PM$_{2.5}$ measured in the years between 2012 and 2016 [17],

The district was taken as the unit of analysis. In this study, 24 districts of Lima were included: Ate, Barranco, Carabayllo, Chorrillos, Comas, El Agustino, Independencia, La Molina, La Victoria, Lima, Lince, Los Olivos, Puente Piedra, Rímac, San Borja, San Isidro, San Juan de Lurigancho, San Juan de Miraflores, San Luis, San Martín de Porres, Santiago de Surco, Surquillo, Villa el Salvador, and Villa María del Triunfo.

The data of PM$_{2.5}$ were for a population of 7,029,238 and a population density of 241,623 people per square kilometer. PM2.5 data were obtained from the National Meteorology and Hydrology Service of Peru (SENAMHI). SENAMHI has ten stations that records PM2.5 daily concentrations in Lima. Data was obtained as a part of an agreement between SENAMHI and Universidad Peruana Cayetano Heredia as
part of the Regional GEOHealth Hub centered in Peru. Details of the construction of database were published previously [17].

Data on the population and surface areas of the provinces and altitude of the capitals of the provinces in Peru were obtained from the Peruvian Center for planning website (https://www.ceplan.gob.pe/informacion-sobre-zonas-y-departamentos-del-peru/).

In the 24 districts, there were 94,273 COVID-19 cases and 1,987 deaths. The case-fatality rate by COVID-19 was 2.58% in Peru and 1.93% in Lima. In the 24 districts of Lima (Peru), the number of food markets was 948. The data from the COVID-19 database of the Open Data website of Peru (https://www.datosabiertos.gob.pe/group/datos-abiertos-de-covid-19) was used to analyze the information on COVID-19 deaths and SARS-CoV-2-positive individuals.

The study protocol was approved by the Institutional Committee for Ethics and Research of the Universidad Peruana Cayetano Heredia (SIDISI code: 202647). This research was a secondary database analysis and therefore did not involve direct contact with study participants. There are no indentification of persons in the database, thereby guaranteeing the total confidentiality and anonymity of the data.

**Statistical analysis**

Data were managed in the MS Excel 2016 program. The STATA v14.0 statistical package (StataCorp, College Station, TX, USA) was used for analysis and ArcGis 10.5 was used for maps construction. First, the average amounts of PM$_{2.5}$ were calculated by each district from 2012 to 2016. Data on the age at infection and at death are presented as mean ± standard deviation, and the differences between the pair of means were calculated by the Student’s $t$-test. The number of COVID-19 cases and deaths by each district was evaluated overall and by each sex.

We explored distinct linear models to assess the relationship of the reported positive cases and deaths, by sex and the sex ratio, at the district level of the province of Lima.

As secondary objective, we assessed the association between number of food markets per district and cases and deaths due to COVID-19. Data from the number of food markets in each district were obtained from a survey in 2016 (www.inei.gob.pe/media/MenuRecursivo/publicaciones_digitales/Est/Lib1447/libro.pdf).

The association between the COVID-19 case-fatality rate (deaths/cases of COVID-19*100) and previous PM$_{2.5}$ exposure was evaluated by using linear regression controlled by age, sex and number of food markets per district. Statistical significance was considered at $p < 0.05$.

**Results**
By June 12, 2020, Peru had 220,749 SARS-CoV-2 positive cases and 6,308 deaths. Lima had 128,700 SARS-CoV-2 positive cases and 2,382 deaths due to COVID-19. Among all of the identified positive cases and COVID-19 deaths, 59.1% \((N = 130,462)\) and 71.1% \((N = 4,485)\), respectively, were men. The number of deaths in the 24 districts studied represents 94.8% of all COVID-19 deaths in Lima.

The national COVID-19 case-fatality rate was 2.58% and was 1.93% for Lima. The mean age at infection was 20 years lower than the age at death due to COVID-19. The patterns at the country and Lima Metropolitan area were similar. Women were infected and succumbed at later ages than men (Table 1).

| Statistical variables          | Age among men (years) | Age among women (years) |
|-------------------------------|-----------------------|-------------------------|
| Cases at country level        | 42.93 ± 16.88         | 43.17 ± 17.69*          |
| \(n = 130,333\)               | \(n = 90,256\)        |
| Cases at Lima level           | 43.01 ± 16.90         | 43.67 ± 17.96*          |
| \(n = 72,992\)               | \(n = 50,613\)        |
| Deaths at country level       | 64.51 ± 13.85         | 66.68 ± 14.91*          |
| \(n = 4,047\)                | \(n = 1,643\)         |
| Deaths at Lima level          | 64.43 ± 14.12         | 67.37 ± 14.47*          |
| \(n = 1695\)                 | \(n = 687\)           |

Data are mean ± SD. *\(p < 0.01\), with regard to the values in men.

The mean concentrations of PM\(_{2.5}\) from 2012 to 2016 for the 24 districts evaluated in this study are shown in Fig. 1A. The lighter red zone refers to lower levels of PM and the darkest tone refers to the highest level of this pollutant.

The incidence of COVID-19 cases and deaths are shown in Fig. 1B and 1C, respectively. The highest incidence of cases and deaths occurred in the districts located to the north of the city compared with the other zones evaluated. The COVID-19 case-fatality rates (Deaths/Cases*100) in Lima are shown in Fig. 1D, and the abundance of food markets per district is shown in Fig. 1E. Moreover, the largest numbers of markets were present in the districts with the highest COVID-19 incidence of cases and deaths (north of the city).

Higher PM\(_{2.5}\) levels were associated with the higher incidence of COVID-19 cases and deaths in 24 districts of Metropolitan Lima (Figs. 2A and 2B). However, the case-fatality rate did not increase with the increasing levels of PM\(_{2.5}\) (Fig. 2C).
Similarly, a higher number of food markets were linearly associated with the higher number of cases and mortality of COVID-19 ($p < 0.01$, Fig. 3A and $p < 0.01$, Fig. 3B, respectively).

The association between the number of food markets with the cases and mortality of COVID-19 persisted when cases ($R^2 = 0.25; r = 0.49; p < 0.01$) and deaths ($R^2 = 0.33; r = 0.58; p < 0.01$) were adjusted by population density. Furthermore, the case-fatality rate was associated with the increased number of food markets ($p < 0.05$; Fig. 3C).

The number of food markets per district did not correlate with PM$_{2.5}$ ($\mu$g/m$^3$) ($Y = 0.033x + 21.05; R^2 = 0.04; r = 0.21; p > 0.05$). This suggests that PM$_{2.5}$ and the number of food markets were independently associated with the spread of COVID-19; moreover, the higher number of food markets was associated with an increased case-fatality rate whereas the higher PM$_{2.5}$ level did not increase the fatality rate (data not shown).

Furthermore, the higher the number of food markets per district, the higher was the incidence of COVID-19/population density ($y = 0.03x^{0.63}; r = 0.58; p < 0.01$). The higher the number of food markets per district, the higher was the COVID-19 mortality/population density*100 ($Y = 0.04x^{0.73}; r = 0.66; p < 0.001$; data not shown).

The increasing PM$_{2.5}$ levels were not associated with specific age at infection, deaths, or the age at death/age at infection for COVID-19 ($p > 0.05$; Figs. 4A, 4B, and 4C).

Table 2
The association between the COVID-19 cases/population density and previous PM$_{2.5}$ concentrations in the 24 districts of Lima

| COVID-19 case/population density | Crude coefficient | 95% CI      | Adjusted coefficient | 95% CI      |
|----------------------------------|-------------------|-------------|----------------------|-------------|
| PM$_{2.5}$                       | 0.083**           | 0.050 0.115 | 0.070**              | 0.034 0.107 |
| Sex ratio                        | −3.133*           | −5.329 −0.937 | −2.157               | −5.127 0.812 |
| Age                              | −0.080            | −0.181 0.021 | 0.047                | −0.064 0.158 |
| Food markets                     | 1.269             | −0.259 2.796 | 0.242                | −0.973 1.457 |

*p < 0.05; **p < 0.01.

The model was adjusted for the PM$_{2.5}$ level, sex ratio (female cases: male cases), food markets (number of food markets per district and age [years] at the COVID-19 diagnosis). Data for the PM$_{2.5}$ level ($\mu$g/m$^3$) correspond to the average data per district obtained daily from 2012 to 2016.

The GLM analysis showed that the increasing levels of PM$_{2.5}$ ($\mu$g/m$^3$) in the previous years (2012–2016) was associated with the higher incidence of COVID-19 in the 24 districts of Lima that were included in the
study. This was observed after adjusting the sex ratio, age at onset, and the number of food markets per district (Table 2). Table 3 shows that PM2.5 was associated with deaths/population density after controlling age, sex and number of food markets. The case-fatality rate (deaths/cases*100) after controlling for different variables was not associated with regard to the increasing levels of PM$_{2.5}$ (Table 4).

### Table 3
The association between the COVID-19 deaths/population density and previous PM$_{2.5}$ concentrations in the 24 districts of Lima

| COVID-19 deaths/population density | Crude coefficient | 95% CI | Adjusted coefficient | 95% CI |
|-----------------------------------|-------------------|--------|----------------------|--------|
| PM$_{2.5}$                        | 0.0016**          | 0.0008 | 0.0023               | 0.0014*| 0.0006 | 0.0023 |
| Sex ratio                         | 0.019             | -0.005 | 0.044                | 0.009  | -0.010 | 0.029  |
| Age                               | -0.001            | -0.002 | 0.000                | 0.000  | -0.001 | 0.002  |
| Food markets                      | 0.029             | -0.002 | 0.060                | 0.024  | -0.007 | 0.055  |

*p < 0.05; **p < 0.01.

The model was adjusted for the PM$_{2.5}$ level, sex ratio (female deaths: male deaths), food markets (number of food markets per district and age [years] at the moments of deaths by COVID-19). Data for the PM$_{2.5}$ level (µg/m$^3$) correspond to the average data per district obtained daily from 2012 to 2016.

### Table 4
Association between the COVID-19 case-fatality rate and previous PM$_{2.5}$ concentrations in the 24 districts of Lima

| COVID-19 fatality rate | Crude coefficient | 95% CI | Adjusted coefficient | 95% CI |
|------------------------|-------------------|--------|----------------------|--------|
| PM$_{2.5}$             | -0.014            | -0.056 | 0.029                | -0.022 | -0.067 | 0.023  |
| Sex ratio              | -0.303            | -2.569 | 1.963                | -2.027 | -5.651 | 1.596  |
| Age                    | 0.043             | -0.049 | 0.135                | 0.107  | -0.029 | 0.242  |
| Food markets           | 1.082             | -0.257 | 2.422                | 1.112  | -0.370 | 2.595  |

*p > 0.05.

The model was adjusted for PM$_{2.5}$ level, sex ratio (female cases: male cases), and food markets (number of food markets per district and age [years] at the COVID-19 diagnosis). Data for the PM$_{2.5}$ level (µg/m$^3$) correspond to the average data per district obtained daily from 2012 to 2016.

**Discussion**
This study showed that exposure to high levels of PM$_{2.5}$ in the years preceding the COVID-19 pandemic was associated with the higher incidence and mortality of COVID-19 but without affecting the case-fatality rate (Deaths/cases*100) in Metropolitan Lima – a city that is considered one of the most polluted in Latin America [9]. This suggests that the current incidence of COVID-19 is associated with a chronic exposure to air pollution. The association was maintained including after controlling by age, sex and number of food markets.

This is an important finding aimed to explain why cases of COVID-19 increased in Lima despite Peru had one of the earliest COVID-19 lockdowns in Latin America applying a quarantine, with much of the activities closed (schools, universities, churches, ban of public events) soon after the first case of COVID-19 was detected. However, three months later Peru and particularly Lima, the capital of the republic is the second country with higher amount of COVID-19 cases after Brazil.

Different from the approach in Brazil, Peru was one of the first countries to initiate social distancing soon after the first case of COVID-19 was reported. However, despite this, the number of COVID-19 cases has increased over time, reaching approximately 250,000 cases in June 2020.

A previous systematic analysis showed that the incidence of and the risk of morbidity and mortality from COVID-19 increase with chronic and acute exposure to air pollution, particularly to PM (PM$_{2.5}$ and PM$_{10}$) and nitrogen dioxide [18].

The values of PM$_{2.5}$ ranged for all districts from 14.50 to 41.69 µg/m$^3$, all of which were higher than the annual mean value declared by the WHO (10 µg/m$^3$). Thus, as it was previously shown that PM$_{2.5}$ was associated with an increasing risk for respiratory infectious diseases [12], the present situation with the COVID-19 spread demonstrates an increasing trend. We have assessed the association with long-term PM$_{2.5}$ exposure; however, the impact of short-term exposure needs to be addressed in further research.

An analysis of the distribution of COVID-19 cases worldwide demonstrates a strong asymmetry [19, 20]. This is exactly the pattern that we have observed in Metropolitan Lima. From the 24 districts assessed, those with higher PM$_{2.5}$ concentrations during 2012–2016 showed more COVID-19 incidence than did those with less concentrations of the pollutants (Supplementary Table 1). In addition, Lima has 58.3% of the national cases, but Lima represents only 28% of the total Peruvian population.

Human pathogenic corona viruses, which include SARS-CoV-2 that is responsible for COVID-19, bind to their target cells through the angiotensin-converting enzyme 2 (ACE2) receptor, which is expressed by epithelial cells of the lung, intestine, kidney, and blood vessels [21]. It is possible that PM$_{2.5}$ may induce the elevation of ACE2 activity.

Active cigarette smoking up-regulates ACE-2 expression in the lower airways, which may partially explain the increased risk of severe COVID-19 in these populations [22]. If air pollutants act similarly as
agents released during smoking, it is probable that individuals with chronic exposure to these compounds would have low ACE2 activity or greater susceptibility to the infection [23].

This study in Metropolitan Lima that used data of PM$_{2.5}$ from 2012 and 2016 for 24 districts showed that the case-fatality rate did not increase with the increasing values of PM$_{2.5}$. This is an interesting finding because a crude analysis of the data showed that deaths are higher when PM$_{2.5}$ concentrations are higher. However, when the data are calculated as the number of deaths/number of cases due to COVID-19 (case-fatality rate), there was no observable association with PM$_{2.5}$. However, the results suggest that PM$_{2.5}$ does not affect the case-fatality rate. This is in agreement with the data observed in New York after short-term exposure to air pollutants [6].

The national COVID-19 case-fatality rate was 2.58%, and at the district level for Lima, it was 1.93%. The highest rate in the rest of Peru respect to Lima may reflect the deficiencies in the healthcare system in the different provinces of Peru. The COVID-19 case-fatality rate was higher in men and increased with age, thus confirming previous results [24].

In average, the age at infection was around 42 years in Peru. After end of quarantine, it is possible that age at infection will lowered. This due to that more of young people will be exposed.

At national and at province level (Lima), the age at infection was 20 years lower than the age at death due to COVID-19. This higher mortality risk for older people has been reported previously [25, 26]. In our study, the association between older age and COVID-19 mortality risk was unaffected by increasing levels of PM$_{2.5}$, suggesting that the factors that explain the higher mortality risk with age are independent of PM$_{2.5}$ exposure. In fact, PM$_{2.5}$ did not modify the COVID-19 case-fatality rate in Lima.

There is evidence of the role of PM pollutants in SARS-CoV-2 transmission. PM$_{2.5}$ and other small PM can act as disease vectors and facilitate the airborne transmission of viable virus particles, and these have been incriminated in the spread of measles and SARS [27].

Social distancing is an important preventable measure to decrease the spread of COVID-19. This was demonstrated in 28 European countries, where the most probable point of change in the course of the COVID-19 epidemic showed a dose-response association of the observed flattening of the epidemic curve with an increasing social distancing index (SDI). Countries in the highest SDI quartile achieved a statistically significant decline in the incidence and prevalence of the epidemic [28].

In Brazil, according to a recent report, social distancing measures that were adopted by the population appeared effective, particularly when implemented in conjunction with the isolation of cases and quarantining of contacts [29].

In numerical simulations, in a city within Brazil, three scenarios were compared: first was the vertical distancing policy, where only older people are distanced; the second involved the horizontal distancing policy where all age groups adhere to social distancing; and the third involved a control scenario wherein
no intervention was undertaken to distance people. Horizontal distancing, if applied with the same intensity in all age groups, significantly reduced the total number of infected people by "flattening the disease growth curve"; however, vertical distancing or non-distancing did not show this effect [30].

Doubtless, social distancing measures appear to be the most effective intervention to slow the disease spread of COVID-19. Though studies unanimously confirm the mitigating effect of social distancing on disease spread, the reported effectiveness varies from 10% to a more than 90% reduction in the number of infections [31]. The changes of mobility in public places, such as retail and recreation centers (e.g., restaurants, cafes, theaters, etc.), grocery stores and pharmacies, transit hubs (e.g., airports, bus stations, subways, etc.), and parks, are the most important determinants of the disease-transmission rate [31].

In Peru, some specific factors could contribute to the spread of COVID-19 during quarantine. These include the easy availability of food markets, banks, and public transport. In Peru, the food markets remained open during the quarantine period to ensure food availability for the population.

According to the findings of this study, in districts where there were more markets, there were higher numbers of cases and deaths. This may explain the high spread of the COVID-19 cases in Lima, in a situation in which individuals are susceptible to the virus by previous exposure to air pollutants.

It is well known that the highest risk of SARS-CoV-2 transmission occurs prior to symptom onset. A recent paper provides evidence of the effectiveness of mask use, disinfection, and social distancing in the prevention of COVID-19 [32].

In this study, the number of markets was unrelated to the PM$_{2.5}$ concentration, which suggests that both factors are independently associated with the spread of COVID-19. Moreover, after controlling for different variables including number of food markers, PM2.5 still remains associated to the number of cases of COVID-19.

From a long-term perspective, the reduction of air contamination should be considered a part of the integrated approach for sustainable development, human health protection, and for reducing the spread of a disease during an outbreak, epidemic, or pandemic. However, although reducing air pollution is important to reduce morbidity and mortality due to different diseases, the findings of this study suggest also the importance of social isolation to reduce the incidence of COVID-19 [33]. The magnitude of contagion in the food markets is an example that policies that are aimed at reducing crowding could be important for preventing the spread of COVID-19.

The limitations of the study are lack of data on number of people attending the food markets during the quarantine period. We were also unable to obtain data on people attending banks, and public transport within the same period.

The study makes a significant contribution to the literature because the findings indicate that higher PM2.5 levels are associated with higher incidence and mortality of COVID-19. However, the case-fatality
rate did not increase with the increase in PM2.5 levels.

The findings of this study are generalizable to regions with similar population density and PM2.5 levels in the setting of respiratory epidemics or future pandemics. This study will be a support tool for decision-making in the country’s health policy, since having a study in which PM 2.5 is associated by district, age, sex, markets of stocks in the number of cases of COVID-19 and deceased, will allow to rethink the measures used by the Peruvian government, and other countries characterized by high air pollution.

In conclusion, the present study demonstrated that the higher rates of spread of COVID-19 in Metropolitan Lima (Peru) were associated to the previous long-term PM$_{2.5}$ exposure. Men and older people were at higher risk of death due to COVID-19. Reduction of air pollution since a long term perspective, and social distancing are needed to prevent spreads of virus outbreak. These results must be taken into account by officers of the Governments to be applied in the health policies aimed to prevent or reduce epidemic viral spread. The strategies taken to confront the pandemic must consider previous environmental indicators to intensify efforts in areas with higher air pollution.

**Abbreviations**

ACE2
angiotensin-converting enzyme 2
CI
Confidence interval
COVID-19
Disease caused by the severe acute respiratory syndrome corona virus 2 (SARS-CoV-2)
°C
centigrade degree

Figures
Figure 1

The distribution of air pollution and COVID-19 cases in Lima. A) particulate matter ≤2.5 µm (PM2.5), B) Incidence of COVID-19 cases, C) Incidence of COVID-19 deaths, D) COVID-19 fatality rate (Deaths/Cases*100), and E) abundance of food markets. Environmental data are expressed as µm/m3 and refers to the mean values for 2012-2016. The distribution data for COVID-19 were obtained from the Ministry of Health of Peru (COVID-19 data updated until June 12, 2020).
Figure 2

The association between PM2.5 and Log (cases of COVID-19/population density) (A), Log (deaths per COVID-19/population density) (B), and fatality rates \times 100 (C) in 24 districts of Metropolitan Lima. The population of the district was ascertained from the values reported in the census of 2017. This number was not corrected based on estimation of growth.
Figure 3

The association between the number of food markets per district and Log (cases of COVID-19/population density) (A), Log (deaths per COVID-19/population density) (B), and fatality rates *100 (C) in 24 districts of Metropolitan Lima.
Figure 4

The association between PM2.5 (µg/m^3) and age (years). (A) Age at SARS-CoV-2 infection, (B) age at death due to COVID-19, and (C) age at death/age at confirmation of COVID-19 in 24 districts of Metropolitan Lima. The population of the district was ascertained from the values reported in the census of 2017. This number was not corrected based on estimation of growth.
