This manuscript was compiled on May 25, 2020

The weaponization of digital communications and social media to conduct disinformation campaigns at immense scale, speed, and reach presents new challenges to identify and counter hostile influence operations (IO). This paper presents an end-to-end framework to automate detection of disinformation narratives, networks, and influential actors. The framework integrates natural language processing, machine learning, graph analytics, and a novel network causal inference approach to quantify the impact of individual actors in spreading IO narratives. We demonstrate its capability on real-world hostile IO campaigns with Twitter datasets collected during the 2017 French presidential elections, and known IO accounts disclosed by Twitter. Our system detects IO accounts with 96% precision, 79% recall, and 96% area-under-the-PR-curve, maps out salient network communities, and discovers high-impact accounts that escape the lens of traditional impact statistics based on activity counts and network centrality. Results are corroborated with independent sources of known IO accounts from U.S. Congressional reports, investigative journalism, and IO datasets provided by Twitter.

Causal inference | Networks | Machine-learning | Social media | Influence operations

Though propaganda is an ancient mode of statecraft, the weaponization of digital communications and social media to conduct disinformation campaigns at previously unobtainable scales, speeds, and reach presents new challenges to identify and counter hostile influence operations (1–5). Before the internet, the tools used to conduct such campaigns adopted longstanding—but effective—technologies. For example, Mao’s guerrilla strategy emphasizes—“propaganda materials are very important. Every large guerrilla unit should have a printing press and a mimeograph stone.” Today, many powers have exploited the internet to spread propaganda and disinformation to weaken their competitors. For example, Russia’s official military doctrine calls to “[e]xert simultaneous pressure on the enemy throughout the enemy’s territory in the global information space” (6).

Online influence operations (IO) are enabled by the low cost, scalability, automation, and speed provided by social media platforms on which a variety of automated and semi-automated innovations are used to spread disinformation (1, 2, 4). Situational awareness of semi-automated IO at speed and scale requires a semi-automated response capable of detecting and characterizing IO narratives and networks, and estimating their impact either directly within the communications medium, or more broadly in the actions and attitudes of the target audience. This arena presents a challenging, fluid problem whose measured data is comprised of large volumes of human- and machine-generated multimedia content (7), many hybrid interactions within a social media network (8), and actions or consequences resulting from the IO campaign (9). These characteristics of modern IO can be addressed by recent advances in machine learning in several relevant fields: natural language processing (NLP), semi-supervised learning, and network causal inference.

This paper presents a framework to automate detection and characterization of IO campaigns. The novel contributions of the paper are:

1. An end-to-end system to perform narrative detection, IO account classification, network discovery, and estimation of IO causal impact;
2. A method for detection and quantification of causal influence on a network (8); and
3. Application of this approach to genuine hostile IO campaigns and datasets, with classifier and impact estimation performance curves evaluated on confirmed IO networks. IO accounts are corroborated using publicly available datasets, U.S. Congressional reports, and reports from investigative journalists. Our system discovers salient network communities and high-impact accounts in spreading propaganda. The framework integrates natural language processing, machine learning, graph analytics, and novel network causal inference to quantify the impact of individual actors in spreading IO narratives. To the extent possible, classifier performance is compared to other online account classifiers.

Framework

The end-to-end system framework collects contextually relevant data, identifies potential IO narratives, classifies accounts based on their behavior and content, constructs a narrative network, and estimates the impact of accounts or networks in spreading specific narratives (Fig. 1). First, potentially relevant social media content is collected using the Twitter public application programming interface (API) based on keywords, accounts, languages, and spatiotemporal ranges. Second, distinct narratives are identified using topic modeling, from

Significance Statement

Hostile influence operations (IO) that weaponize digital communications and social media pose a rising threat to open democracies. This paper presents a system framework to automate detection of disinformation narratives, networks, and influential actors. The framework integrates natural language processing, machine learning, graph analytics, and novel network causal inference to quantify the impact of individual actors in spreading the IO narrative. We present a classifier that detects IO accounts with 96% precision, 79% recall, and 96% AUPRC, demonstrated on real social media data collected for the 2017 French presidential election and known IO accounts disclosed by Twitter. Our system also discovers salient network communities and high-impact accounts that are independently corroborated by U.S. Congressional reports and investigative journalism.

which narratives of interest are identified by analysts. In general, more sophisticated NLP techniques that exploit semantic similarity, e.g., transformer models (10), can be used to identify salient narratives. Third, accounts participating in the selected narrative receive an IO classifier score based on their behavioral, linguistic, and content features. The second and third steps may be repeated to provide a more focused corpus for IO narrative detection. Fourth, the social network of accounts participating in the IO narrative is constructed using their pattern of interactions. Fifth, the unique impact of each account—measured using its contribution to the narrative spread over the network—is quantified using a novel network causal inference methodology. The end product of this framework is a mapping of the IO narrative network where IO accounts of high impact are identified.

Methodology

**Targeted Collection.** Contextually relevant Twitter data are collected using the Twitter API based on keywords, accounts, languages, and spatiotemporal filters specified by the authors. For example, during the 2017 French presidential election, keywords include the leading candidates, #Macron and #LePen, French election-related issues, including hostile narratives expected to harm specific candidates, e.g., voter abstention (11) and unsubstantiated allegations (12). Because specific narratives and influential IO accounts are discovered subsequently, they offer additional cues to either broaden or refocus the collection. In the analysis described in the preceding subsection, 28 million Twitter posts and nearly 1 million accounts potentially relevant to the 2017 French presidential election were collected over a 30-day period preceding the election, and a total of nearly 800 million tweets and information on 13 million distinct accounts were collected.

**Narrative Detection.** Narratives are automatically generated from the targeted Twitter data using a topic modeling algorithm (13). First, accounts whose tweets contain keywords relevant to the subject, or exhibit pre-defined, heuristic behavioral patterns within a relevant time period are identified. Second, content from these accounts are passed to a topic modeling algorithm, and all topics are represented by a collection, or bag of words. Third, interesting topics are identified manually. Fourth, tweets that match these topics above a pre-defined threshold are selected. Fifth, a narrative network is constructed with vertices defined by accounts whose content matches the selected narrative, and edges defined by retweets between these accounts. In the case of the 2017 French elections, the relevant keywords are: ‘Macron’, ‘Leaks’, ‘election’, or ‘France’; the languages used in topic modeling are English and French.

**IO Account Classification.** IO account classification is performed with a semi-supervised machine-learning approach built using the open source libraries scikit-learn and Snorkel (14, 15), and soft labeling functions based on heuristics of IO account metadata, content, and behavior. The feature space comprises behavioral characteristics, profile characteristics, languages used, and the 1- and 2-grams used in tweets; full details are provided in S1C, and feature importances are illustrated in the ‘Results’ section in Fig. 4. The classifier is trained using data from the narrative networks constructed as described in the preceding subsection and using truth from the publicly available Twitter Elections Integrity dataset (7). Dimensionality reduction and classifier algorithm selection is performed by optimizing precision-recall performance over a broad set of dimensionality reduction approaches, classifiers, and parameters (see S1C). In the results section, dimensionality reduction is performed with Extra-Trees (ET) (14) and the classifier is the Random Forest (RF) algorithm (14). Ensemble tree classifiers learn the complex concepts of IO account behaviors and characteristics without over-fitting to the training data through a collection of decision trees, each representing a simple concept using only a few features.

**Network Discovery.** The narrative network—a social network of participants involved in discussing and propagating a specific narrative—is constructed from their observed pattern of interactions. In the ‘Results’ section, narrative networks are constructed using retweets. Narrative networks and their pattern of influence are represented as graphs whose edges represent strength of interactions. The (directed) influence from (account) vertex $v_i$ to vertex $v_j$ is denoted by the weighted edge $a_{ij}$. For simplicity in the sequel, network vertex $v_i$ is also referred to as $i$. The influence network is represented by the adjacency matrix $A = (a_{ij})$. Because actual influence is not directly observable, the influence network is modeled as a random variable with Poisson distribution parameterized by the observed evidence of influence. Specifically, influence $a_{ij}$ is modeled with distribution $a_{ij} \sim \text{Poisson}(\lambda_{ij} = \text{number of past interactions})$, as counts of interactive influence in real-world networks (16).

**Impact Estimation.** Impact estimation is based on a novel method that quantifies each account’s unique causal contribution to the overall narrative propagation over the entire network. It accounts for social confounders (e.g., community membership, popularity) and removes their effects from the causal estimation. This approach is based on the network potential outcome framework (17), itself based upon Rubin’s causal framework (18). Mathematical details are provided in SI.D.

The fundamental quantity is the network potential outcome of each vertex, denoted $Y(Z, A)$, under exposure to the narrative from the source vector $Z$ via the influence network $A$. Precisely, $Z$ is a binary N-vector of narrative sources (a.k.a. treatment vector). In this study, vertices are user accounts, edges represent influence as described in...
‘Methodology: Network Discovery’, and the potential outcomes are the number of tweets in the narrative. The impact \( \zeta \) of each vertex on the overall narrative propagation is defined using network potential outcome differentials averaged over the entire network:

\[
\zeta(z) \overset{def}{=} \frac{1}{N} \sum_{i=1}^{N} (Y_i(Z = z_{ii}, A) - Y_i(Z = z_{ii}, \bar{A})).
\]

This causal estimand is the average difference between the individual outcomes with \( v_i \) as a source such that \( z_{ii} := (z_1, \ldots, z_i := 1, \ldots, z_N) \), versus \( v_i \) not a source, \( z_{ii} := (z_1, \ldots, z_i := 0, \ldots, z_N) \). This impact is the average (per vertex) number of additional tweets generated by an user’s participation in the narrative. The source is said to be uniquely impactful if it is the only source.

It is impossible to observe the outcomes at each vertex with both exposure conditions under source vectors \( z_{ii} \) and \( z_{ii} \): therefore, the missing potential outcomes must be estimated, which can be accomplished using a model. After estimating the model parameters from the observed outcomes and vertex covariates, missing potential outcomes in the causal estimand \( \zeta \) can be imputed using the fitted model. Potential outcomes are modeled using a Poisson generalized linear model (GLM) with the canonical log link function and linear predictor coefficients \( \tau, \gamma, \beta, \mu \) corresponding to the source indicator \( Z_i \), n-hop exposure vector \( s_i^n \), the covariate vector \( x_i \), and the baseline outcome. The covariate vector \( x_i \) includes the potential social confounders such as popularity and community membership. The GLM model for the potential outcomes is

\[
\log \lambda_i = \tau Z_i + \sum_{n=0}^{N_{hop}} \prod_{k=1}^{n} \gamma_k s_i^n + \beta^T x_i + \mu + e_i
\]

with \( Y_i(Z, A) \sim \text{Poisson}(\lambda_i) \), where \( \tau z_i \) represents the primary effect from the source, \( \sum_{n=0}^{N_{hop}} \prod_{k=1}^{n} \gamma_k s_i^n \) represents the accumulative social influence effect from n-hop exposures \( s_i^n \) to the source and \( \gamma_i \) captures the decay of the effect over each additional hop, \( \beta^T x_i \) is the effect of the unit covariates \( x_i \) including potential social confounders such as popularity and community membership, \( \mu \) is the baseline effect on the entire population, and \( e_i \sim \text{Normal}(0, \sigma^2) \) provides independent and identically distributed variation for heterogeneity between the units. The amounts of social exposure at the nth hop are determined by \( (A^n)^T Z \). This captures narrative propagation via all exposure to sources within the narrative network. Diminishing return of additional exposures is modeled using (nonnegative) log-exposure, \( s_i^n = \log((A^n)^T Z + 1) \).

### Results

**Targeted Collection.** The targeted collection for the 2017 French presidential election includes 28,896,185 potentially relevant tweets and 999,883 distinct accounts, all collected over a 30-day period preceding the election on 7 May 2017. Targeted collections for several other IO scenarios were also collected during 2017, resulting in a dataset with 782,678,201 tweets and 12,723,995 distinct accounts. Most of these data do not concern the French election, but will provide negative examples for IO classifier training.

**Narrative Detection.** Narratives immediately preceding the election are generated automatically by dividing this broad content into language groups, restricting the content and time period to election-related posts within one week preceding the election’s media blackout date of 5 May 2017, and filtering accounts based on interaction with non-French media sites pushing narratives expected to harm specific candidates. Topic modeling (13) is applied to the separate English and French language corpora, and the resulting topics are inspected by the authors to identify relevant narratives. Two such narratives are illustrated in Fig. 2 by the most-frequent word and emoji usage appearing in tweets included within the topic. From the English corpus (\( N = 152,203 \)), 15 topics are generated; from the French (\( N = 1,070,158 \)), 30 topics. These automatically generated topics correspond closely to allegations claimed to be spread by WikiLeaks, candidate Marine Le Pen, and others (19, 20). Two topics, one in English and one in French, pertaining to unsubstantiated financial allegations (Fig. 2) will be used to identify accounts involved in spreading these narratives, independent of whether the accounts were used for narrative detection.

**IO Account Classification.** Twitter published IO truth data containing 50,230 known IO account identities and their multimedia content (7). This dataset is used along with heuristic rules to train a semi-supervised classifier (15) using the approach described in the ‘Methodology’ section, and the rulesets are detailed in SL.C. The classifier is trained using content from three distinct sources: known IO accounts that have tweeted on any topic at least once in either English or French (true examples), and a combination of randomly
selected topically relevant accounts and topically neutral accounts (presumptively false examples). There are 3,151 known IO accounts in our dataset that have tweeted in English or French. Because IO accounts represent a small fraction of all Twitter accounts, e.g., 9–15% of all Twitter accounts are estimated to be bots (21), 15,000 presumptively false examples are randomly selected with 5,000 each of three false classes: topically relevant accounts that tweeted at least once in English, at least once in French, and topically neutral, randomly chosen from the general dataset.

**Precision–Recall (P-R) Performance.** P-R performance of the classifier is computed via cross validation using the same dataset with a 90 : 10 split, averaged over 20 rounds (Fig. 3). Because the number of known cases is limited, weak supervision from the heuristic Snorkel labeling functions is used to identify true examples before cross validation (15). All training is performed with Snorkel-labeled data, and cross validation is performed both using both Snorkel-labeled data (solid curves in Fig. 3) and omitting Snorkel positives (dashed curves). Sensitivity to language-specific training data is also computed by restricting topically relevant, false examples to specific languages. All classifiers exhibit comparably strong performance, and small differences in relative performance is consistent with the authors’ expectations. All classifiers detect IO accounts with 96% precision and 79% recall at a nominal operating point, 96% area-under-the-PR-curve (AUPRC), and 8% equal-error rate (EER). The English-only and French-only classifiers perform slightly better (nominally 0–3%) than the combined language model, consistent with the expectation that models with greater specificity outperform less specific models. This strong classifier performance will be combined with additional inferences—narrative networks, community structure, and impact estimation—to identify potentially influential IO accounts involved in spreading particular narratives.

With this dataset, the original feature space has dimension 1,896,163: 17 behavior and profile features, 61 languages, and 1,896,085 1- and 2-grams. Section SI:C lists the behavior, profile features, and language features. Grid search over feature dimensionality is used to identify the best feature set for dimensionality reduction: 10 behavioral and profile features, 30 language features, and 500 1- and 2-grams. The most important features used by the classifier are illustrated by the relative sizes of feature names appearing in the word cloud of Fig. 4. Note that the most important features for IO account classification are independent of topic, and pertain instead to account behavioral characteristics and frequency of languages other than English or French. This topic independence suggests the potential applicability of the classifier to other IO narratives.

**Classifier Performance Comparisons.** Several online IO account classifiers exist that are often cited in the press (23), notably Botometer (formerly BotOrNot) (24) and Bot Sentinel (25). We compare the P-R performance of our IO classifier to both Botometer and Bot Sentinel. This comparison is complicated by three factors: (1) neither Botometer nor Bot Sentinel have published classifier performance against known IO accounts; (2) neither project has posted open source code; and (3) known IO accounts are immediately suspended, which prevents post hoc analysis with these online tools.

Therefore, a proxy for known IO accounts must be used for performance comparisons. We use the observation that there exists strong correlation between likely IO accounts in our narrative network and membership in specific, distinguishable communities independently computed using an MCMC-based blockmodel (22). Community membership of accounts in the French language narrative network (Fig. 2) are illustrated in Fig. 5. Five distinct communities are detected, three of which are identified to have promoted Macron allegation narratives. The other two narratives promote pro-Macron and pro-abstention narratives. Accounts in this narrative network are classified on a 0–1 scale of their similarity to known IO accounts, shown in Fig. 6. Comparing Figs. 5 and 6 shows that the great majority of accounts in the ‘Macron allegation’ communities are classified as highly similar to known IO accounts, and conversely, the great majority of accounts in the pro-Macron and pro-abstention communities are classified as highly dissimilar to known IO accounts. This visual comparison is quantified by the account histogram illustrated in SI Fig. S7.

Using membership in these ‘Macron allegation’ communities as a proxy for known IO accounts, P-R performance is computed for our IO classifier, Botometer and Bot Sentinel (Fig. 7). Given this narrative network and truth proxy, both Botometer and Bot Sentinel perform nominally at random chance of 63% precision, the fraction of presumptive IO accounts. Our IO classifier has precision performance of 82–85% over recalls of range 20–80%, which exceeds random chance performance by 19–22%. Observed performance differences are hypothesized to be caused by the intended design of Botometer or Bot Sentinel, which is to detect general bot activity, not necessarily the specific IO behavior on which our classifier is trained.

**Network Discovery.** Tweets that match topics of Fig. 2 are extracted from the collected Twitter data. French-language tweets made in the week leading up to the blackout period, 28 April through 5 May 2017, are checked for similarity to the French language topic. To ensure the inclusion of tweets on the #MacronLeaks data dump, which occurred on the eve of the French media blackout, English-language tweets from 29 April through 7 May 2017 are compared to the English topic. In total, the French topic network consists of 6,927 accounts and the
English topic network consists of 1,897 accounts. For visual clarity, network figures are generated on the most active accounts, 459 in the French and 752 in the English networks.

**Impact Estimation.** Estimation on the causal impact of each account in propagating the narrative is performed by computing the estimand in Eq. (1), considering each account as the source. Unlike existing propagation methods on network topology (26), causal inference accounts also for the observed counts from each account to capture how each source contributes to the subsequent tweets made by other accounts. Results demonstrate this method’s advantage over traditional impact statistics based on activity count and network topology alone.

Impact estimation and IO classification on the English narrative network (Fig. 2) are demonstrated in Fig. 8. Graph vertices represent Twitter accounts sized by the causal impact score (i.e. posterior mean of the causal estimand) and colored by the IO classifier using the same scale as Fig. 6. Redness indicates account behavior and content like known IO accounts, whereas blueness indicates the opposite. This graph layout reveals two major communities involved in narrative propagation of unsubstantiated financial allegations during the French election. The large community at the top left comprises many accounts whose behavior and content is consistent with known IO accounts. The relatively smaller community at the lower right includes many mainstream media accounts that publish reports on this narrative. Within this mainstream journalism-focused community, the media accounts AP, ABC, RT, and Reuters are among the most impactful, consistent with expectation. The most remarkable result, however, is that known IO accounts are among the most impactful among the large community of IO-like accounts. The existence of these IO accounts was known previously (7, 27), but not their impact in spreading specific IO narratives. Also note the impactful IO accounts (i.e. the large red vertices) in the upper community that appear to target many benign accounts (i.e. the white and blue vertices).

A comparison between the causal impact and traditional impact statistics is provided in Table 1 on several representative and/or noteworthy accounts highlighted in Fig. 8. The prominent @RT_America, a major Russian media outlet, and @JackPosobiec, a widely reported (20) account in spreading this narrative, corroborate our estimate of their very high causal impact scores. This is also consistent with their early participation in this narrative, high tweet counts, high number of followers, and large PageRank centralities. Conversely, @UserA and @UserB have low impact statistics, and also receive low causal impact scores as relatively non-impactful accounts.

| Screen name | T | RT | F | 1st time | PR | CI* |
|-------------|---|----|---|----------|----|-----|
| @RT_America | 39 | 8  | 386k| 12:00    | 2706| 1.55|
| @JackPosobiec | 28 | 123| 23k | 01:54 | 4690| 1.43|
| @UserA† | 8  | 0  | 1.4k| 22:53 | 44  | 0.14|
| @UserB† | 12 | 15 | 19k | 12:27 | 151 | 0.41|
| @Pamela_Moore13 | 10 | 31 | 56k | 18:46 | 97  | 1.65|
| @TEN_GOP | 12 | 42 | 112k| 22:15 | 191 | 1.38|

*Anonymized screen names of currently active accounts

Known IO account (7–9, 27) @Pamela_Moore13’s involvement in this narrative illustrates the relative strength of the causal impact estimates in identifying relevant IO accounts. @Pamela_Moore13 stands out as one of the prominent accounts addressing this narrative. Yet ‘her’ other impact statistics (T, RT, F, PR) are distinct, and comparable in value to the not-impactful account @UserB. Additionally, known IO accounts @TEN_GOP and @TXCowboys-Rawk (7, 27, 28), and Sputik writer @CassandraRules (29) all stand out for their relatively high causal impact and IO account classifier scores (Fig. 9). Causal impact estimation is shown to find high-impact accounts that do not stand out using traditional impact statistics. This estimation is accomplished by comparing the impact of the narrative propagates over the influence network, and its utility is demonstrated using data from known IO accounts on known IO narratives. Additional impact estimation results are provided in SI.E.

**Influential IO Account Detection.** The outcome of the automated framework proposed in this manuscript is the identification of influential IO accounts in spreading IO narratives. This is accomplished by combining IO classifier scores with IO impact scores for a specific narrative (Fig. 9). Accounts whose behavior and content appear like known IO accounts and whose impact in spreading an IO narrative is relatively high are of potential interest. Such accounts appear in the upper-right side of the scatterplot illustrated in Fig. 9. Partial validation of this approach is provided by the known IO accounts discussed above. Many other accounts in the upper-right side of Fig. 9 have since been suspended by Twitter, and some at the time of writing are actively spreading conspiracy theories about the 2020 coronavirus pandemic (30). These currently-active accounts participate in IO-aligned narratives across multiple geo-political regions and topics, and no matter their authenticity, their content is used hundreds of times by known IO accounts (7) (SI.F). As an effective tool for situational awareness, the framework in this manuscript can alert social media platform providers and the public of influential IO accounts and networks, and the content they spread.

**Discussion**

We present a framework to automate detection of disinformation narratives, networks, and influential actors. The framework integrates NLP, machine-learning, graph analytics, and novel network causal inference to quantify the impact of individual actors in spreading the IO narrative. Application of this framework to several authentic influence operation campaigns run during the 2017 French elections provides alerts to likely IO accounts that are influential in spreading IO narratives. Our results are corroborated by independent press reports, U.S. Congressional reports, and Twitter’s Elections Integrity public dataset. The detection of IO narratives and high-impact accounts is
demonstrated on a dataset comprising 29 million Twitter posts and 1 million accounts collected in 30 days leading up to the 2017 French elections. We also measure and compare the classification performance of a novel semi-supervised classifier for IO accounts involved in spreading specific IO narratives. At a representative operating point, our classifier performs with 96% precision, 79% recall, 96% AUPRC, and 8% EER. Our classifier precision is shown to outperform two online Bot detectors by 20% (nominally) at this operating point, conditioned on a network-community-based truth model. A novel causal network inference approach is used to quantify the impact of accounts spreading specific narratives. This method accounts for the influence network topology and the observed volume from each account, and moves the effects of social confounders (e.g. community membership, popularity). We demonstrate the approach’s advantage over traditional impact statistics based on activity count (e.g. tweet and retweet counts) and network topology (e.g. network centralities) alone in discovering high-impact IO accounts that are independently corroborated.

A. Additional Background. Exploitation of social media and digital communications by world powers to achieve their political objectives (1–18) at unprecedented scales, speeds, and reach presents a rising threat, especially to democratic societies (1, 3, 5, 6, 19, 20). Situational awareness of influence campaigns and a better understanding of the mechanism behind social influence (4, 21) provide necessary capabilities for potential responses (2, 7, 22). In other applications, social influence can even be harnessed to promote knowledge and best practices in public policy settings for social good (23).

B. Narrative Detection Using Topic Modeling. Tweets were collected that are potentially relevant to a representative scenario in which actual IO accounts were expected to be active: the 2017 French election. A large dataset containing both English and French language corpora was created from this collection. From these corpora, 15 English language topics and 30 French topics are generated automatically using a topic modeling algorithm (24). The set of generated English topics includes several relevant to the French election as well as topics on U.S. politics and other world events. A selection of the English topics is shown in Table S1. The first topic relates to unsubstantiated financial allegations; this is the topic used for network discovery in the main paper. The generated French topics are predominantly focused on the French election, including a French language version of unsubstantiated financial allegations. A subset of these topics is shown in Table S2. Note that in both tables and the sequel, the notation ‘:emoji_symbol:’ specifies an emoji symbol.

C. IO Account Classifier and Feature Engineering. The data used to train the IO classifier includes 3,151 known IO accounts released by Twitter and 15,000 randomly selected accounts from three subsets of the targeted collection dataset: accounts that tweeted on the French election in English, accounts that tweeted on the French election in French, and topic- and language-neutral accounts. Each subset contributes 5,000 accounts to the training dataset. Multiple feature categories are used: account behavior features, language features across all content, and features derived from the content itself.

C.1. Heuristics for Semi-Supervised Learning. Because the quantity of known IO accounts is relatively small, a semi-supervised training strategy based on Snorkel (25) is employed. In this approach, training data from known truth are augmented with weakly labeled training data provided by heuristic ‘labeling functions’ (Table S3), and the learning model learns and incorporates labeling function inaccuracies. Our Snorkel labeling functions are based on reported characteristics of IO account behavior, content, and metadata (26–29). These Snorkel heuristics were then refined by applying them to a small validation set. One hundred accounts were randomly selected out of the 5,000 that tweeted on the French election in English. An attempt was made to label each account as either a real person or an IO account by examining their Twitter profile and current tweets. However, many accounts were either suspended or difficult to determine with confidence to which category they belong. Of these 100 randomly chosen accounts, 24 were labeled as IO accounts, 31 were labeled non-IO, and the remaining were discarded from the validation set.

Though 9–15% of all Twitter accounts are estimated to be bots (30), it is possible that the charged topics analyzed in the main paper contain a higher proportion of bots and possible IO accounts. To account for this possibility in classifier training, all accounts that have a 70% or higher likelihood of being IO-like, according to Snorkel, are labeled as IO accounts, and accounts below the 70% threshold are labeled as non-IO accounts. This results in roughly 30% of the training accounts on the French election and 15% of the topic-neutral accounts being labeled IO accounts. The proportions of each training data subset that falls above the threshold is given for three different points in Table S4.

C.2. Classifier Design Comparisons. Classifier design is conducted by comparing the relative performance of four different classifier models, Random Forest (31), Logistic Regression, xgBoost (32), and SVM (33), and two dimensionality reduction approaches, Extra Trees (34) and SVD. The performance of the all classifier design combinations over a grid of classifier parameters is evaluated via averaged cross validation over twenty 90:10 splits. Cross validation is performed both over 10% of all training data (Fig. S2) and after discarding all accounts that were labeled as IO-like by Snorkel heuristics (Fig. S1). Of the eight combinations and for both methods of cross validation, the best performing method is composed of dimensionality reduction using the Extra Trees method followed by a Random Forest classifier (Figs. S1, S2). We compare the P-R and ROC curves for Random Forest, Extra Trees across the two methods of cross validation in Figs. S3 and S4, respectively. The standard deviation from cross-validation is shown in Fig. S3, in which it is seen that the maximum standard deviation for when all data is used is 1.6%, and 3.2% when Snorkel positives are omitted. Although xgBoost with Extra Trees performs as well as the Random Forest, Extra Trees classifier when the validation set includes 10% of all training data, it performs significantly worse when the Snorkel-labeled IO accounts are discarded from the validation set. Further, examination of the performance of xgBoost, Extra Trees on accounts in the narrative networks shows that the classifier scores tend to be skewed towards extremes, rather than being distributed more evenly across the interval [0, 1] (Fig. S6).

C.3. Sensitivity Analysis and Performance Statistics. Snorkel is used to provide additional, semi-supervised training data by labeling IO positives. A Snorkel score is computed for each account, and in the main paper, all accounts that exceed a score of 70% are treated as IO truth within classifier training. This 70% threshold is determined by both a sensitivity analysis that compares classifier performance across a range of metrics: precision–recall (P-R) at a fixed classifier score threshold (0.6 based on Fig. S7), area-under-the-PR-curve (AUPRC), the equal-error rate (EER, Table S5), and the fraction of training accounts that are labeled positively by Snorkel (Table S4). Performance is comparable across the three bracketed thresholds considered—50%, 70%, and 90%—though the 50% threshold has the worst performance for most of the statistics. Retaining all training data within cross-validation sets (contra omitting Snorkel positives) is most consistent with the objective of measuring classifier performance on actual accounts within a narrative network. The relative performance comparisons of Table S5 (using all data) and Table S4 show that a 70% threshold has the best AUPRC, best recall, with a small (0.5–1.5%) trade-off in EER and precision, and also the fraction of IO accounts at this threshold is consistent with published estimates of bot activity as discussed in C.1.
C.4. Feature Engineering. The IO classifier is trained on three categories of features: account behavior, languages used in tweets, and all 1- and 2-grams that appear more than 15 times across all account tweets in the training set. Initially, the feature set is composed of 17 behavioral features, 60 language features, and 1.8 million 1- and 2-grams. To limit the per account content used to generate these content features, a maximum of 10,000 randomly selected tweets are chosen from each account. The total number of tweets used in the English and French classifier is 40,155,545.

The standard machine-learning dimensionality reduction step is used to improve classifier performance in problems like this one that have a very large feature space relative to the number of training samples. Grid search optimization is used to determine the best-performing dimensionality reduction approach, and the relative importance of each feature. In the dataset used in the main paper, the Extra Trees algorithm is used to reduce the feature space to 10 behavioral features (Table S6), 30 languages (Table S7), and 500 1- and 2-grams (Table S8). Additionally, the behavioral, language, and 1-and 2-gram feature spaces are each reduced independently of each other to ensure adequate representation by each feature category.

C.5. Classifier Scores versus Account Status. As noted in section C.2, the Random Forest with Extra Trees combination is the best performing classifier model. Its optimality is further justified upon examination of the distribution of the classifier scores across accounts in the French narrative network (Fig. S5). The accounts are divided by current (March 2020) status as reported by the Twitter API: active, suspended, and deleted. The suspended and deleted accounts are skewed toward higher classifier scores, showing a correlation between accounts detected by the classifier and behavior that results in suspension from Twitter.

Although both the Random Forest/Extra Trees and xgBoost/Extra Trees classifiers have near-identical performance in Fig. S2, the latter’s performance on the French narrative network is not nearly as promising. In Fig. S6, the classifier scores over the French narrative network tend towards extremes for all three account status categories, in stark contrast to the more realistic distribution seen in Fig. S5.

C.6. Validation of Community-Based Proxy Truth. As discussed in the main paper section ‘Results: Classifier Performance Comparisons,’ membership in the ‘Macron allegations’ community is a fundamental measure of the French narrative network (main paper, Fig. 6) and is used as a proxy for known IO accounts where independent truth is unavailable. To establish the narratives used by accounts in the ‘Macron allegations’ community, topic modeling is performed on tweets from accounts in the community over the week preceding the media blackout (28 April to 5 May 2017). A selection of the generated topics is given in Table S9. Three representative tweets from each topic are shown in Table S10, which illustrate the stance of accounts within this community. Topic modeling is performed on the tweets in the pro-Macron and pro-Abstention communities over the same time period. A selection from those topics is given in Table S11 and Table S12, respectively.

To validate this proxy assumption and quantify its accuracy in the absence of the underlying truth, we hypothesize that: (1) the ‘Macron allegations’ narrative is used by actual IO accounts in the 2017 French election; and (2) the distribution of known IO accounts is higher in IO narratives. The first hypothesis is confirmed by numerous independent news reports (14, 19, 20, 35) and direct observation (3, 16, 36–38). Though we do not have the ability to independently establish the validity of the second hypothesis, we can show that the validity of our results are consistent with this hypothesis.

The distribution of our classifier scores is computed across both the ‘Macron allegations’ and ‘pro-Macron’/‘pro-abstention’ communities in the French narrative network (Fig. S7). There is a distinct disparity between these histograms. Classifier scores of accounts in the ‘Macron allegations’ community are relatively small at lower (non(IO-like) scores, and rise sharply to very high relative frequencies above a classifier score of 0.6—the expected range of IO-like scores. In contrast, classifier scores across the other communities are more evenly distributed and slightly skewed towards lower (non(IO-like) scores, also expected for narrative network communities dominated by pro-Macron activity.

D. Network Potential Outcome Framework for Causal Inference. Interference takes place in causal inference when the treatment applied to one unit affects the outcomes of other units due to their interactions and influence. An example of rising importance is treating individuals on a social network. This section introduces the mathematical framework of causal inference under network interference (39), used in the main paper’s section ‘Methodology: Impact Estimation.’ Network potential outcomes are the fundamental quantity used to capture various types of causal effects such as network impact in Eq. [1] of the main paper. Realistically, many network potential outcomes will be unobserved and a complete randomization over the different treatment exposures is infeasible, making the estimation of the causal estimands challenging. Bayesian imputation of the missing network potential outcomes provides a natural conceptual solution. Theory for this imputation is developed based on the critical assumptions of unconfounded treatment assignment and an unconfounded influence network, leading to the key ignorability condition for the treatment exposure mechanism. Driven by this theory, a rigorous design and analysis procedure is proposed for causal inference under network interference.

D.1. Introduction. Interference, in the context of causal inference, refers to the situation when the outcome of a ‘unit’ is affected not only by its own treatment, but also by the treatment of other units. Interference on a network of influence, known as network interference, is of rising importance. Common examples are experiments and observational studies on a social network where treatment effects propagate through peer influence, spread of knowledge, or social benefits, etc. This phenomenon is also known as spillover effects and social contagions. The application areas are numerous, e.g. public health, education, and policy (40–43); social media and marketing (44–47); network security (4, 48); and economics (49–51).

Traditionally, interference has been viewed as a nuisance in causal experiments, and earlier works propose experimental designs that render the interference effects ignorable on restricted, simple block structures (52, 53). More recent work detects and estimates interference effects on networks, many of them building on the potential outcome framework (54). To detect network interference effects, Bowers et al. (55) propose hypothesis testing using potential outcome models with specific primary and peer effects, and Athey et al. (56) propose exact p-value tests by constructing artificial experiments on the original experimental units such that the null hypothesis is sharp. To estimate network interference effects, Ugander et al. (57) propose inverse probability weighting when the probability of the specific exposure condition can be computed, Ugander et al. (58) develop a cluster randomization approach that leads to a closed-form solution on the probabilities of specific neighborhood...
exposures, and Sussman and Airoldi (59) propose exclusion restrictions on the potential outcomes and derive design conditions that lead to unbiased estimators. Social confounders present another source of challenge for causal inference under network interference. Early work by Manski (51) demonstrates unidentifiability of the peer effects in the presence of social confounders under linear outcome models. Recent works in causal inference show that confounding social covariates lead to unidentifiability and biased estimates of causal effects (60), especially on social networks (61, 62), and how longitudinal studies (63, 64) and design of experiment for specific peer effects (65) provide a way forward.

D.2. Definitions. The key quantities are the potential outcomes of each unit in the study under different treatment conditions. They serve as the basic building blocks for causal inference in the potential outcome framework. Most existing works assume an absence of interference and a simple binary treatment assignment, which is the Stable Unit Treatment Value Assumption (SUTVA) (66). Under SUTVA, the potential outcomes for each unit i are a function of its own treatment and are denoted as $Y_i(z)$, where $z$ is a binary indicator for whether the treatment is assigned to unit i. The potential outcomes of all N units in an experiment, $Y$, can be partitioned into two vectors of N components: $Y(0)$ for all outcomes under control and $Y(1)$ for all outcomes under treatment. $Y$ can also be partitioned according to whether it is observed. In an experiment, a unit is either under control or under treatment. Therefore, half of all potential outcomes are observed, denoted as $Y_{obs}$. The other half of the potential outcomes are unobserved, denoted as $Y_{mis}$. As a result, causal inference is fundamentally a missing data problem, with a rich body of work on rigorous design and analysis for estimating and imputing the missing outcomes (67).

Under network interference, the potential outcome definitions need to be generalized to encompass the different treatment exposure conditions via the network, starting with the units:

Definition 1 (Finite Population on a Network of Influence). The study takes place on a finite population of N units where their influence on each other is represented as a $N \times N$ influence matrix $A$. Each element of the influence matrix, $A_{ij} \in \mathbb{R}$, represents the strength of influence unit i has on unit j. One may visualize this population network as a graph, $G = (V, E)$, of which the node set $V$ consists of the units of the study ($|V| = N$) and the edge set $E$ represents the zero-one entries of the influence matrix $A$.

The outcomes of each unit not only depend on its own treatment but also on exposure to treatments on other units propagated through the influence network.

Definition 2 (Network Potential Outcomes). Under network interference, the outcomes of a unit i, change according to its exposure to the treatment on the finite population $Z$, through the network of influence $A$. The network potential outcomes of i are denoted as $Y_i(Z, A)$.

Definition 3 (Network Potential Outcome Sets). The entire set of network potential outcomes for unit i is $Y_i = \{ Y_i(Z = z, A = a) \}$ for all $z \in Z$, $a \in A$, where $Z$ is the set of all possible assignments on the closed neighborhood of i and A is the set of all possible influence networks on the closed neighborhood of i. The set of all network potential outcomes on the finite population with N units is $Y = \{ Y_1, Y_2, \ldots, Y_N \}$. $Y$ can also be partitioned based on whether it is observed. In an experiment, for each unit, only one of the numerous possible neighborhood treatment in $Z$ is realized. The set of observed network potential outcomes, typically of size N, is denoted as $Y_{obs}$. Most of the network potential outcomes will be unobserved. The set of unobserved outcomes, its size depending on the size of each unit’s closed neighborhood, is denoted as $Y_{mis}$.

Lastly, covariates $X$ on the network potential outcome units play a vital role in principled design and analysis for estimating and imputing the unobserved outcomes. For k-dimensional covariates on the units, the matrix $X$ has $N \times k$ elements. Under the scope here, the treatment vector $Z$ is limited to binary indicators for treatment versus control, but can be easily generalized for multi-level treatments.

D.3. Bayesian Imputation of Missing Outcomes and Unconfounded Assumptions. Under network interference, most of the potential outcomes in the causal estimands will be unobserved. Furthermore, a complete randomized assignment of the different exposures to neighborhood treatment is typically infeasible, as the structure of the influence network impacts each unit’s chance to receive a certain exposure (68). These make the estimation of causal estimands challenging under network interference. A natural solution is to perform Bayesian imputation of missing potential outcomes. Also known as the Bayesian predictive inference for causal effects, this method has been well established for causal inference in the absence of interference (i.e. SUTVA holds) (69, 70).

As the potential outcomes serve as the building blocks for each causal estimand, computing the posterior distribution of the unobserved potential outcomes also gives the posterior distribution of any causal estimands. In the regular case under SUTVA, the posterior distribution of interest is $P(Y_{mis}|X, Z, Y_{obs})$. Inference of the unobserved potential outcomes from the observed potential outcomes, the unit covariates $X$, and the treatment assignment vector $Z$, is typically done with a potential outcome model. Modeling and inference of this posterior distribution is greatly simplified when the treatment assignment mechanism can be ignored (i.e. $Z$ can be dropped from the posterior). Rubin shows how the unconfounded treatment assignment leads to this ignorability (69, 70).

In the case under network interference, the posterior distribution is on the expanded sets of network potential outcomes and includes the influence network: $P(Y_{mis}|X, Z, A, Y_{obs})$. Similar to the regular case under SUTVA, this posterior can also be greatly simplified when the neighborhood treatment mechanism can be ignored (i.e. both $Z$ and $A$ can be dropped from the posterior). This section shows how the assumptions of unconfounded treatment assignment and unconfounded influence network lead to this extended ignorability. Under network interference, although Bayesian imputation of the missing network potential outcomes offers a practical solution, the procedure needs to respect the key unconfounded assumptions in order to avoid incorrect causal estimates.

Assumption 1 (Unconfounded Treatment Assignment Assumption Under Network Interference). Conditional on the relevant unit covariates $X$ and the influence network $A$, the treatment assignment $Z$ is independent from the potential outcomes $Y$:

$$P(Z|X, A, Y) = P(Z|X, A).$$

[1]
This assumption can be met in real-world experiments through complete randomization of \( Z \) or including possible confounders in the conditional unit covariates \( X \). Sometimes, experiments on a social network target units with certain network characteristics for treatment, in order to achieve a desirable overall outcome. For example, a researcher may target the most influential units (e.g. high degree nodes) in order to maximize peer influence effects. Assumption 1 holds under such treatment assignment strategies because the treatment \( Z \) only depends on the influence network, \( A \), and relevant unit covariates \( X \). This paper estimates the impact of each unit as a potential source (i.e. being treated), so the treatment assignment does not depend on the potential outcomes, satisfying Assumption 1.

**Assumption 2 (Unconfounded Influence Network Assumption Under Network Interference).** Conditional on the relevant unit covariates \( X \), the influence network \( A \) is independent from the potential outcomes \( Y \):

\[
P(A | X, Y) = P(A | X).
\]

This assumption is met if the formation of the influence network has no correlation with the potential outcomes. However, this is often not true in real-world experiments (62). Intuitively, correlation between the potential outcomes and the influence network may arise from certain characteristics of a unit that are correlated with both its outcomes as well as its relationships with other units on the network. Activity level and group memberships are examples of such characteristics. For example, an account’s node degree on the retweet network may be positively correlated with its potential outcomes (i.e. tweet count on the IO narrative) because hubs in the influence network may tweet more in general. Similarly, an account’s membership to an IO community may be positively correlated with its potential outcomes. Therefore, meeting Assumption 2 will likely require including such confounding characteristics in the conditional unit covariates \( X \). A method to achieve this will be formally proposed in Theorem 2, but first, we introduce the ignorability condition.

**Theorem 1 (Ignorable Treatment Exposure Mechanism Under Network Interference).** If the unconfounded treatment assignment assumption and the unconfounded influence network assumption are both met, the treatment exposure mechanism is ignorable and does not enter the posterior distribution of the missing potential outcomes:

\[
P(Y_{\text{mis}} | X, Z, A, Y_{\text{obs}}) = P(Y_{\text{mis}} | X, Y_{\text{obs}}).
\]

Theorem 1 is proved via factorization and application of Assumptions 1 and 2:

\[
P(Y_{\text{mis}} | X, Z, A, Y_{\text{obs}}) = \frac{P(Z | X, A, Y) P(Y | X, A) dY_{\text{mis}}}{\int P(Z | X, A, Y) P(Y | X, A) dY_{\text{mis}}}
= \frac{P(Z | X, A) \int P(Y | X, A) dY_{\text{mis}}}{\int P(Y | X, A) dY_{\text{mis}}}
= \frac{P(Y_{\text{mis}} | X, A) P(Y | X)}{P(Y | X) dY_{\text{mis}}}
= P(Y_{\text{mis}} | X) dY_{\text{mis}}.
\]

Finally, Assumption 2 can be satisfied by conditioning on network parameters through parametric modeling.

**Theorem 2 (Unconfounded Influence Network by Conditioning on Network Parameters).** The unconfounded influence network assumption in Assumption 2, \( P(A | X, Y) = P(A | X) \), is met if:

1. The distribution of the influence network \( A \) can be characterized by a model \( H_G \) with nodal parameters \( X_G \) and population parameters \( \Theta_G \): \( A \sim H_G(X_G, \Theta_G) \);
2. The potential outcomes \( Y \) correlate with the influence network \( A \) only through a subset of the nodal parameters \( \tilde{X}_G \in X_G \) and population parameters \( \tilde{\Theta}_G \);
3. The unit covariates \( X \) contain these network parameters \( \tilde{X}_G \) and \( \tilde{\Theta}_G \).

Theorem 2 leverages the assumption that the influence network \( A \) can be characterized by a model with nodal (i.e. unit-specific) parameters \( X_G \) (e.g. expected degree, community membership, position in the latent space, etc.) and population parameters \( \Theta_G \) (e.g. inter-community interaction, sparsity, etc.). Most if not all of the currently well-known network models in the network inference community can be described in this way, including the latent space models (71), the latent class models such as the membership blockmodels (72–74), degree distribution models (75, 76), and the graphon (77). Typically, only a subset of the nodal parameters, \( \tilde{X}_G \), may be correlated with the potential outcomes, like activity level and community membership in the IO narrative influence network. Some of the population parameters, \( \tilde{\Theta}_G \), like sparsity, may be correlated with the potential outcomes as well. Intuitively, conditioning on these parameters breaks the correlation between the potential outcomes and the influence network, therefore meeting the unconfounded influence network assumption. Often, these network model parameters are not readily observed, but they can be estimated from the social network data collected in the experiment. This is similar in spirit to work by Frangakis and Rubin (78) on latent ignorability where the treatment mechanism is ignorable by conditioning on the latent compliance covariate.

D.4. Theory to Practice: Design and Analysis Under Network Interference. Driven by the theoretical framework developed above, the experimental and analytical procedure for Bayesian imputation of missing potential outcomes and causal estimands is summarized in the following steps.

1. Define the population, the treatment, and the network potential outcomes. Collect prior information on the underlying influence network. This can be from data on interactions between the units (e.g., emails, tweets, phone calls, etc.) or a survey on the social network (e.g., list of relationships). One may only have partial or prior information on the influence network, in which case the network will need to be imputed during analysis.

2. Propose an appropriate network model and estimate the model parameters using the observed influence network or the prior distribution on the influence network.

3. Propose an appropriate potential outcome model including all the possible confounding covariates, guided by Assumptions 1 and 2, and Theorem 2, in order to meet the ignorable treatment exposure mechanism condition specified in Theorem 1. Some of these may be the estimated network parameters from the previous step and the possible treatment assignment confounders. Perform Bayesian inference to compute the posterior distributions of the potential outcome model parameters, jointly with the influence network if it is not fully known, as typically is the case.

4. Using the posterior distributions from the step above, impute the missing network potential outcomes in the causal estimands of interest, and finally arrive at the posterior distribution of the causal estimands, the quantity of interest.

This procedure accounts for potential confounders through covariate adjustment, where accuracy depends on the adequacy of the potential outcome model. Additional robustness to model mis-specification can be achieved through balancing of confounding covariates across different treatment exposure conditions in the causal estimand. This can be done via treatment design in experiments or matching in observational studies, as a desirable future expansion on this framework.

E. Impact Estimation on the #MacronLeaks Narrative. Further support of this framework’s efficacy is provided by its application to a well-known, highly visible, and distinctive IO narrative network defined by a simple Twitter hashtag, #MacronLeaks (35, 38) (Fig. S8). Vertex color in Fig. S8 indicates the number of times each account tweets the hashtag #MacronLeaks; vertex size is the in-degree, i.e., the number of retweets received by each account. Compared to the financial allegation narrative detected via topic modeling in the main paper, this narrative is on a related but more focused event of the leaking of candidate Macron’s emails. While many IO narratives do not align nicely with a hashtag and need to be detected via topic modeling, the #MacronLeaks narrative is an instance where the hashtag became a prominent signature for the narrative. The hashtag was widely used in many tweets and retweets, as reflected by the higher magnitude impact statistics in Table S13, compared to Table 1 in the main paper. Among the accounts with high estimated impact, there exists independent confirmation of the prominence of the two accounts @wikileaks and @JackPosobiec in pushing the #MacronLeaks narrative (35). The relatively high causal impact of these accounts shown in Table S13 is consistent with independently reported articles about this narrative. Further, a new finding is the high-impact spreading of this IO narrative by the known IO account @Pamela_Moore13 (36, 37).

Comparison between impact statistics in Table S13 highlights the advantage of causal impact estimation in quantifying impact over activity- and topologically based statistics such as retweet (RT) volume and PageRank centrality (79, 80). The limitation of activity count statistics as indicators for impact is seen in @UserA and @UserC, both having high tweet and retweet counts but little impact due to their positions on and connectivities to the network with low centrality. Follower count and PageRank centrality clearly highlight @wikileaks’s impact on the network, which is consistent with its high causal impact. However, accounts such as @JackPosobiec, @UserB, and known IO account @Pamela_Moore13 have only a medium level of PageRank centrality, but high causal impact. @JackPosobiec, being one of the earliest participant, has been reported as a key source in pushing the #MacronLeaks narrative (35). @UserB serves as a bridge into the predominantly French-speaking subgraph (the cluster seen in the middle of Fig. S8). Causal impact is able to detect these prominent accounts that do not stand out in other impact statistics by modeling the narrative propagation on the network. Unlike existing propagation methods on network topology (81) alone, causal inference accounts also for the observed outcomes at each node.

F. Influential IO-like Content 2017 vs. 2020. Many of the high-impact accounts with behaviors and content similar to known IO accounts (upper-right corner of main paper Fig. 9) have been suspended by Twitter since 2017. However, several remain actively engaged at the time of writing in narratives also used by IO accounts in 2020 (12, 82, 83). For example, high-impact, IO-like accounts that posted on the 2017 French election narrative network (main paper Figs. 2, 6) are actively posting three years later on COVID-19 conspiracy theories. Additional validation of this paper’s approach is suggested by examining how the content of such active accounts has been used by known IO accounts. Inspecting a small-but-representative sample of 3 active accounts appearing in the upper-right corner of Fig. 9 of the main paper shows that content from these accounts has been used by known IO accounts hundreds of times (9 in one case, 472 in another, and 589 in another) for each of these active accounts (37). Furthermore, we observe that our classifier is robust to whether or not these accounts are directly retweeted by known IO accounts. Only 5 tweets from these 3 representative accounts (1, 1, and 3 tweets for each account) were included in our classifier as ‘positive’ examples used by known IO accounts, whereas 555 tweets (total for all 3) were retweeted by accounts included as negative examples in the training data. Because the classifier training data is comprised of 40 million tweets, the presence of 5 tweets from these specific accounts does not have a large effect on their positive classification, especially that their content appears 555 times in non-IO ‘negative’ training data. Finally, note that we do not assert or imply that these are IO accounts, but merely observe that their content and behavior is quantifiably similar to known IO accounts, independent of their authenticity. This observation is consistent with the fact that content from these specific accounts has also been used hundreds of times (as retweets) by known IO accounts (37, 84).

Table S4. Proportion of training data subsets labeled as IO accounts by Snorkel heuristics.

|                        | 50% threshold | 70% threshold | 90% threshold |
|------------------------|---------------|---------------|---------------|
| French election, English | 38%           | 32%           | 23%           |
| French election, French | 34%           | 28%           | 22%           |
| Topic and language neutral | 30%           | 15%           | 8%            |
Fig. S1. Classifier P-R performance across many classifier algorithms. Validation set selected from known IO accounts and negatively labeled Snorkel data.
Fig. S2. Classifier P-R performance across many classifier algorithms. Validation set selected from all data.
Fig. S3. RF / ET classifier precision–recall (P-R) performance with cross-validation error over twenty 90 : 10 splits; all data ( ), and Snorkel positives omitted ( ).

Maximum standard deviation (gray region, ——) is 0.016 and 0.032, respectively.
Fig. S4. RF / ET classifier receiver operating characteristic (ROC) performance: true positive rate (TPR, a.k.a. recall) versus false positive rate (FPR); all data (—), and Snorkel positives omitted (—). Classifier EER is determined by the point at which $1 - TPR = FPR$ (dashed gray curve, ——).
Table S5. Sensitivity comparison, Snorkel thresholds for IO labeling and cross validation set selection.

| Threshold | Precision | Recall | AUPRC | EER |
|-----------|-----------|--------|-------|-----|
| 50% all data | 94.3% | 78.7% | 95.8% | 10.5% |
| 50% Snorkel positives | 88.2% | 91.6% | 96.9% | 6.1% |
| 70% all data | 95.6% | 78.9% | 96.4% | 8.1% |
| 70% Snorkel positives | 91.6% | 90.3% | 96.6% | 5.6% |
| 90% all data | 97.1% | 73.5% | 96.0% | 7.6% |
| 90% Snorkel positives | 95.8% | 90.5% | 97.4% | 5.0% |
