Bounds on poloidal kinetic energy in plane layer convection

A. Tilgner

Institute of Geophysics, University of Göttingen, Friedrich-Hund-Platz 1, 37077 Göttingen, Germany

(Dated: 4 October 2018)

A numerical method is presented which conveniently computes upper bounds on heat transport and poloidal energy in plane layer convection for infinite and finite Prandtl numbers. The bounds obtained for the heat transport coincide with earlier results. These bounds imply upper bounds for the poloidal energy which follow directly from the definitions of dissipation and energy. The same constraints used for computing upper bounds on the heat transport lead to improved bounds for the poloidal energy.

I. INTRODUCTION

Transport in turbulent flows, for instance heat flow across a turbulent convecting layer, cannot be computed analytically but has to be computed numerically or measured experimentally. However, rigorous analytical calculations can provide us with upper bounds on the transport. The oldest work finding upper bounds on turbulent dissipation seems to go back to Hopf\textsuperscript{1}. Bounds for turbulent heat transport (which can also be expressed in terms of dissipation) appeared later in different forms. A series of papers including refs. \textsuperscript{2–4} leads to one method for obtaining upper bounds, called MHB method for short in this paper, and Constantin and Doering presented another method closely related to Hopf’s original work\textsuperscript{5,6} denoted as CDH method in the sequel. These two methods yield identical bounds if the best bounds obtainable within each method are compared. More recently, Seis\textsuperscript{7} came up with another approach which obtains bounds from a very compact derivation.

The quality of the bounds obtained from the CDH method depends on the choice of a certain function, usually called background field. The optimal background field yielding the lowest upper bounds has again to be determined numerically. A direct computation from the Euler-Lagrange equations (as for instance in ref. \textsuperscript{8} for infinite Prandtl number convection) is cumbersome, which has prompted several authors\textsuperscript{9–11} to search for alternatives. This paper presents yet another alternative. It employs the same constraints on the turbulent flow derived from the Navier-Stokes equation as previous methods but uses a reformulation which allows to numerically find the optimal background field through the solution of a semidefinite program (SDP) which is simpler to implement than the SDP directly derived from the CDH method solved in ref. \textsuperscript{11}.

Apart from these technical issues, the main purpose of this paper is to explore the possibility of obtaining interesting bounds on energies. Previous work on bounds focused on dissipation or transport, but other properties are of interest as well. A bound on dissipation implies a bound on energy set by the maximal amount of energy which can exist in the least dissipative flow mode without violating the bound on dissipation. This argument is only based on the definitions of energy and dissipation and does not take into account that the flow field has to obey the Navier-Stokes equation. It is therefore of interest to see whether the constraints used in deriving bounds on dissipation can lead to improved bounds on energies. Since the expression for energy contains fewer derivatives and is less singular than the
dissipation, one can hope that it is in some way simpler to find tight bounds on energies.

Section II starts with a precise statement of the problem. The general idea of the employed method is worked out in section III taking as example upper bounds for the heat transport in infinite Prandtl number convection. The results are extended to general Prandtl number in section IV. Section V finally presents bounds on the poloidal energy.

II. STATEMENT OF THE PROBLEM

Consider a plane layer of thickness $h$ with bounding planes perpendicular to the $z-$axis, infinitely extended in the $x-$ and $y-$directions, and with gravitational acceleration acting in the direction of negative $z$. The layer is filled with fluid of density $\rho$, kinematic viscosity $\nu$, thermal diffusivity $\kappa$, and thermal expansion coefficient $\alpha$. Top and bottom boundaries are held at the fixed temperatures $T_{\text{top}}$ and $T_{\text{top}} + \Delta T$, respectively. We will consider the equations of evolution immediately in nondimensional form, choosing for units of length, time, and temperature deviation from $T_{\text{top}}$ the quantities $h$, $h^2/\kappa$ and $\Delta T$. With this choice, the equations within the Boussinesq approximation for the fields of velocity $v(\mathbf{r}, t)$, temperature $T(\mathbf{r}, t)$ and pressure $p(\mathbf{r}, t)$ become:

\begin{align}
\frac{1}{\text{Pr}} \left( \partial_t \mathbf{v} + \mathbf{v} \cdot \nabla \mathbf{v} \right) & = -\nabla p + \text{Ra} \theta \mathbf{\hat{z}} + \nabla^2 \mathbf{v} \\
\partial_t \theta + \mathbf{v} \cdot \nabla \theta - v_z & = \nabla^2 \theta \\
\nabla \cdot \mathbf{v} & = 0
\end{align}

In these equations, $T = \theta + 1 - z$, so that $\theta$ represents the deviation from the conduction profile. The Prandtl number $\text{Pr}$ and the Rayleigh number $\text{Ra}$ are given by

$$\text{Pr} = \frac{\nu}{\kappa}, \quad \text{Ra} = \frac{g \alpha \Delta T h^3}{\kappa \nu}$$

and $\mathbf{\hat{z}}$ denotes the unit vector in $z-$direction. The conditions at the boundaries $z = 0$ and $z = 1$ on the temperature are that $\theta = 0$. Both stress free and no slip conditions will be investigated. At stress free boundaries, $\partial_z v_x = \partial_z v_y = v_z = 0$, whereas $\mathbf{v} = 0$ on no slip boundaries.

It is convenient to decompose $\mathbf{v}$ into poloidal and toroidal scalars $\phi$ and $\psi$ so that $\mathbf{v} = \nabla \times \nabla \times (\phi \mathbf{\hat{z}}) + \nabla \times (\psi \mathbf{\hat{z}})$ which automatically fulfills $\nabla \cdot \mathbf{v} = 0$. The $z-$component of the
curl and the $z$-component of the curl of the curl of eq. (1) yield the equations of evolution for $\phi$ and $\psi$,

$$\frac{1}{\Pr} \left( \partial_t \Delta_2 \phi + \hat{z} \cdot \nabla \times \nabla \times [(\nabla \times \mathbf{v}) \times \mathbf{v}] \right) = \nabla^2 \Delta_2 \phi - Ra \Delta_2 \theta$$  \hspace{1cm} (5)

$$\frac{1}{\Pr} \left( \partial_t \Delta_2 \psi - \hat{z} \cdot \nabla \times [(\nabla \times \mathbf{v}) \times \mathbf{v}] \right) = \nabla^2 \Delta_2 \psi$$  \hspace{1cm} (6)

with $\Delta_2 = \partial^2_x + \partial^2_y$. For brevity, $\mathbf{v}$ is not replaced by its expression in terms of $\phi$ and $\psi$ in these equations. The stress free boundary conditions translate into $\phi = \partial_z^2 \phi = \partial_z \psi = 0$ and the no slip boundary conditions become $\phi = \partial_z \phi = \psi = 0$.

In the following, several types of averages will be important: the average over the entire volume, denoted by angular brackets without subscript, the average over an arbitrary plane $z = \text{const}$., denoted by $\langle ... \rangle_A$, the average over a particular plane $z = z_0$, denoted by $\langle ... \rangle_{A,z=z_0}$, and the average over time, which will be signaled by an overline.

The dot product of $\mathbf{v}$ with eq. (1), followed by a volume average, leads to

$$\partial_t \langle \frac{1}{2} v^2 \rangle = -\Pr Ra \langle \theta \Delta_2 \phi \rangle - \Pr \langle (\hat{z} \times \nabla) \nabla^2 \phi \rangle^2 + \langle |\nabla \partial_x \psi|^2 + |\nabla \partial_y \psi|^2 \rangle.$$  \hspace{1cm} (7)

Note that $v_z = -\Delta_2 \phi$. Multiplication of eq. (2) with $\theta$ and a subsequent volume average yields

$$\partial_t \langle \frac{1}{2} \theta^2 \rangle = -\langle \theta \Delta_2 \phi \rangle - \langle |\nabla \theta|^2 \rangle.$$  \hspace{1cm} (8)

The average of eq. (2) over planes is noted for later reference:

$$\partial_t \langle \theta \rangle_A = \langle \partial_z (\theta \Delta_2 \phi) \rangle_A + \langle \partial^2 \theta \rangle_A.$$  \hspace{1cm} (9)

We will seek below bounds on the Nusselt number $\text{Nu}$, defined as the time averaged heat transport divided by the heat conducted if the fluid is at rest. $\text{Nu} - 1$ can be determined from the vertical derivative of $\theta$ averaged over top or bottom boundaries: $\text{Nu} - 1 = -\langle \partial_z \overline{\theta} \rangle_{A,z=0} = -\langle \partial_z \overline{\theta} \rangle_{A,z=1}$. Integration of eq. (9) from $z = 0$ to any finite $z$, followed by time averaging, shows that $\langle \theta \Delta_2 \phi \rangle_A + \langle \partial_z \overline{\theta} \rangle_A$ is identical at all height $z$, and in particular equal to $\langle \partial_z \overline{\theta} \rangle_{A,z=0}$ because $\Delta_2 \phi = 0$ at $z = 0$. An integration of $\langle \theta \Delta_2 \phi \rangle_A + \langle \partial_z \overline{\theta} \rangle_A = \langle \partial_z \overline{\theta} \rangle_{A,z=0}$ over all $z$ yields $\langle \theta \Delta_2 \phi \rangle = \langle \partial_z \overline{\theta} \rangle_{A,z=0} = -\text{Nu} + 1$, which yields an alternative expression for $\text{Nu} - 1$, and by virtue of eq. (8) one also has $\text{Nu} - 1 = \langle |\nabla \theta|^2 \rangle$. 

4
The second quantity for which we will seek bounds is the energy in the poloidal part of the velocity field, $E_{\text{pol}}$, given by

$$E_{\text{pol}} = \langle \frac{1}{2} (\nabla \times \nabla \times (\hat{z} \times \nabla \phi))^2 \rangle. \quad (10)$$

Because of the volume average, $E_{\text{pol}}$ is strictly speaking an energy density.

Considerable simplification results in the limit of infinite Prandtl number. The time derivative and the advection term disappear from eq. (1) in this limit. Eq. (6) then implies that $\psi = 0$ and the momentum equation becomes a diagnostic equation for $\phi$ alone:

$$\nabla^2 \nabla^2 \Delta_2 \phi - \text{Ra} \Delta_2 \theta = 0. \quad (11)$$

The temperature equation and the expressions for Nu and $E_{\text{pol}}$ as well as the boundary conditions are not affected by setting $\text{Pr}$ to infinity.

**III. BOUNDS FOR CONVECTION AT INFINITE PRANDTL NUMBER**

**A. The method**

This section explains the essence of the bounding method. Convection at infinite Prandtl number serves as a simple example for more general problems. The objective function $Z$ defines the quantity for whose time average $\overline{Z}$ we wish to find a bound. For example, the choice $Z = \langle |\nabla \theta|^2 \rangle$ will yield bounds on $\overline{Z} = \text{Nu} - 1$.

For infinite $\text{Pr}$, eq. (11) allows us to eliminate $\phi$ in favor of $\theta$ and we are left with equations for $\theta$ only. The objective function $Z$ also depends only on $\theta$. Let us choose test functions $\varphi_n(z)$, $n = 1...N$ which depend on $z$ only and project onto them the temperature equation (2):

$$\partial_t \langle \varphi_n \theta \rangle = \langle \varphi_n \partial_z (\theta \Delta_2 \phi) \rangle + \langle \varphi_n \nabla^2 \theta \rangle. \quad (12)$$

We now build a functional $G(\lambda_1...\lambda_N, \lambda_R, \theta)$ as a linear combination of the right hand sides of the equations (12) and (8):

$$G(\lambda_1...\lambda_N, \lambda_R, \theta) = \sum_{n=1}^{N} \lambda_n \left[ \langle \varphi_n \partial_z (\theta \Delta_2 \phi) \rangle + \langle \varphi_n \nabla^2 \theta \rangle \right] + \lambda_R \left[ \langle \theta \Delta_2 \phi \rangle + \langle |\nabla \theta|^2 \rangle \right]. \quad (13)$$

The variable $\phi$ has been left in the expression for $G$ for better readability but it does not appear as an argument of $G$ because of eq. (11) and $\Delta_2 \phi = \text{Ra}(\nabla^2 \nabla^2)^{-1} \Delta_2 \theta$, where $(\nabla^2 \nabla^2)^{-1}$ is the inverse bi-Laplacian equipped with the boundary conditions for $\phi$. 
Assume that we know a set of coefficients $\lambda_1, \ldots, \lambda_N, \lambda_R$ and an additional number $\lambda_0$ such that for our chosen objective function $Z(\theta)$ and all fields $\theta(\mathbf{r})$ obeying the boundary conditions for $\theta$, the following inequality holds:

$$-Z + \lambda_0 + G(\lambda_1, \ldots, \lambda_N, \lambda_R, \theta) \geq 0.$$  \hspace{1cm} (14)

If this inequality is satisfied for every admissible $\theta$, it is in particular satisfied by a solution of the equation of evolution. For such a solution and a set of $\lambda$'s as specified above, we then have

$$0 = G - \sum_{n=1}^{N} \lambda_n \partial_t \langle \varphi_n \theta \rangle + \lambda_R \partial_t \langle \frac{1}{2} \theta^2 \rangle$$

$$\geq Z - \lambda_0 + \partial_t \left[ -\sum_{n=1}^{N} \langle \varphi_n \theta \rangle + \lambda_R \langle \frac{1}{2} \theta^2 \rangle \right].$$  \hspace{1cm} (15)

Taking the time average of the expression to the right of the inequality sign, we find $\overline{Z} \leq \lambda_0$. We see that we obtain an upper bound for $\overline{Z}$ as soon as we know a set of coefficients $\lambda$ so that eq. (14) is satisfied. The terms in $G$ are at most quadratic in $\theta$. If we wish to find upper bounds for dissipation or energy, $Z$ is quadratic in $\theta$, too. If $\theta$ is discretized, say, by spectral decomposition, the left hand side of inequality (14) is a quadratic form in the expansion coefficients of $\theta$. Finding the sharpest bound on $\overline{Z}$ then amounts to minimizing $\lambda_0$ subject to the condition that the matrix appearing in the discretized form of inequality (14) be positive semidefinite. This problem has precisely the form of a semidefinite program.

In order to arrive at an implementable formulation, we have to select a discretization for $\theta$ and test functions $\varphi_n$. A decomposition into $N$ Chebychev polynomials $T_n$ for the $z$--direction and into plane waves in $x$ and $y$ is chosen as a representation of $\theta$:

$$\theta = \sum_{n=1}^{N} \sum_{k_x} \sum_{k_y} \hat{\theta}_{n,k_x,k_y} T_n(2z-1) e^{i(k_x x + k_y y)}. $$  \hspace{1cm} (16)

The summation limits for $k_x$ and $k_y$ are not specified because they will turn out to be irrelevant. The coefficients $\hat{\theta}_{n,k_x,k_y}$ for any given $k_x, k_y$ are not independent of each other because of the boundary conditions on $\theta$ at $z = 0$ and $z = 1$. Only $N_f$ of the $N$ coefficients are free. In order to enforce $\theta = 0$ at $z = 0$ and $z = 1$, it is enough to set $N = N_f + 2$. However, as reported below, it was found numerically advantageous to also explicitly enforce $\partial^2_z \theta = 0$ at $z = 0$ and $z = 1$ (a relation which follows from eq. (2) and all boundary conditions considered here), in which case $N = N_f + 4$. 

6
The test functions $\varphi_n$ are chosen as delta functions centered at the collocation points in common use in time integration methods based on Chebychev discretization:

$$z_n = \frac{1}{2} \left[ 1 + \cos \left( \pi \frac{n - 1}{N - 1} \right) \right], \quad n = 1...N$$  \hspace{1cm} (17)

$$\varphi_n(z) = \delta(z - z_n).$$  \hspace{1cm} (18)

Inserting all this into eq. (14) leads to an inequality of the form

$$- \sum_{k_x,k_y} x_{k_x,k_y}^* Z_k x_{k_x,k_y} + \lambda_0 + \sum_{n=1}^N \lambda_n \sum_{k_x,k_y} x_{k_x,k_y}^* G_{nk} x_{k_x,k_y} + x_{k_x,k_y}^* \lambda_R E_k x_{k_x,k_y} \geq 0.$$  \hspace{1cm} (19)

The superscripted star denotes complex conjugation. The matrices $Z_k$, $E_k$ and $G_{nk}$ are real. Their entries depend on $k_x$ and $k_y$ only in the combination $k^2 = k_x^2 + k_y^2$ and there are no terms coupling different $k$. Furthermore, these matrices are symmetric. The vectors $x_{k_x,k_y}$ are constructed as $x_{k_x,k_y} = (1, \hat{x}_{1,k_x,k_y}, \hat{x}_{2,k_x,k_y}, \ldots, \hat{x}_{N_f,k_x,k_y})$ where the $\hat{x}_{n,k_x,k_y}$ are linear combinations of the $\hat{\theta}_{n,k_x,k_y}$ in eq. (16). They appear in an expansion analogous to eq. (16) as the coefficients of $N_f$ linear combinations of the first $N$ Chebychev polynomials satisfying the boundary conditions. The 1 in the first component of $x_{k_x,k_y}$ is necessary in order to accommodate the term linear in $\theta$ in the $k = 0$ summand in eq. (19). It also allows us to write $\lambda_0$ as $\sum_{k_x,k_y} x_{k_x,k_y}^* \lambda_0 H_k x_{k_x,k_y}$ with $H_k = 0$ for $k \neq 0$ and all entries of $H_0$ are zero except that $H_{0,1,1} = 1$.

Inequality (19) therefore has the form

$$\sum_{k_x,k_y} x_{k_x,k_y}^* \left[ -Z_k + \lambda_0 H_k + \sum_{n=1}^N \lambda_n G_{nk} + \lambda_R E_k \right] x_{k_x,k_y} \geq 0.$$  \hspace{1cm} (20)

For $\lambda_0$ to serve as an upper bound, this inequality must be satisfied for all $x_{k_x,k_y}$, which requires that $\left[ -Z_k + \lambda_0 H_k + \sum_{n=1}^N \lambda_n G_{nk} + \lambda_R E_k \right]$ be positive semidefinite for all $k$. The SDP to be solved is in summary:

minimize $\lambda_0$

subject to $- Z_k + \lambda_0 H_k + \sum_{n=1}^N \lambda_n G_{nk} + \lambda_R E_k \geq 0$ for all $k$  \hspace{1cm} (21)

where $M \succeq 0$ means that the matrix $M$ is positive semidefinite.

The symmetry about the midplane can be exploited to alleviate the numerical task of solving the SDP. This symmetry suggests to construct linear combinations of the constraints
in the form of equations for \( \partial_t ( \langle \varphi, \theta \rangle \pm \langle \varphi_{N+1-i} \theta \rangle ) , \; i = 1...N/2 \). It turns out that only the equations with the minus sign constrain \( \lambda_0 \), the other equations are redundant. Symmetry affects also the parity of the most dangerous functions which most readily violate the inequality constraint of the SDP. Expanding \( \theta \) in the functions \( T_{n+2}(2z-1) - T_n(2z-1) \), which are by construction zero at \( z = 0 \) and \( z = 1 \), one only needs to retain odd \( n \) for \( k = 0 \) and even \( n \) for \( k \neq 0 \). The other combinations do not affect the best bound.

It may seem like a formidable task to enforce the inequality condition in (21) for all \( k \). In fact, it is not. Barring any special symmetry or degeneracy in the matrices involved, the inequality will hold as a strict inequality for almost all \( k \) and as an equality only for a finite set of \( k \), the active set in the parlance of optimization. The active set tends to be small. As an example, pretend that we are looking for a bound on dissipation so that \( Z = \langle |\nabla \theta|^2 \rangle \). We should be able to prove that dissipation is zero for \( R_a \) below onset. This requires \( \lambda_0 = 0 \). We can find a suitable set of coefficients by setting \( \lambda_1 = \lambda_2 = \ldots = \lambda_N = 0 \) and only \( \lambda_R \neq 0 \). Eq. (14) becomes \( \lambda_R \langle \theta \Delta_2 \phi \rangle + (\lambda_R - 1) \langle |\nabla \theta|^2 \rangle \geq 0 \). The last term suggests that we are best off choosing \( \lambda_R \) positive and large compared with 1, so that the condition

\[
\langle \theta \Delta_2 \phi \rangle + \langle |\nabla \theta|^2 \rangle \geq 0 \tag{22}
\]

needs to be satisfied for all admissible \( \theta \) (\( \phi \) being determined by eq. (11)). The left hand side of eq. (22) is equal to \(-\partial_t \langle \frac{1}{2} \theta^2 \rangle\), so that eq. (22) is nothing but the condition for energy stability. The \( \theta \) which yields the largest possible left hand side is determined from a linear Euler-Lagrange equation with coefficients independent of \( k \), since the left hand side itself has no \( k \) dependent coefficients. The optimal \( \theta \) has therefore a single Fourier component. At the critical Rayleigh number, the inequality condition in (21) is fulfilled with the equality sign for one value of \( k \) and as a strict inequality for all other \( k \). At least at this Ra, the active set contains only one element. As Ra is increased, the active set gradually becomes larger, adding one element after the other.

All results presented in this paper were computed with an automated search for the active set. As one is usually interested in some bound as a function of Ra, start with a small Ra and a tentative active set of two elements: \( k = 0 \), which is always necessary for any \( \lambda_i \neq 0, 1 \leq i \leq N \) because of the last term in eq. (12), and an additional \( k \neq 0 \). Then run an optimization over the nonzero \( k \) which maximizes \( \lambda_0 \), where \( \lambda_0 \) is the result of the
SDP problem

\[
\text{minimize } \lambda_0 \quad \text{subject to } - Z_k + \lambda_0 H_k + \sum_{n=1}^{N} \lambda_n G_{nk} + \lambda_R E_k \succeq 0 \quad \text{for all } k \text{ in the active set}
\]  

This maximization selects the wavenumbers \( k \) which impose the most stringent constraint on \( \lambda_0 \). Once the maximum is found, it remains to check whether the active set is complete. For this purpose, the matrix \( \left[ -Z_k + \lambda_0 H_k + \sum_{n=1}^{N} \lambda_n G_{nk} + \lambda_R E_k \right] \) is assembled for 1000 values of \( k \) regularly spaced on a logarithmic scale for \( k \) between 0.1 and \( 10^4 \), and for each matrix, a Cholesky decomposition is attempted. If the matrix is positive semidefinite at all tested wavenumbers, the calculation advances to the next higher Ra to compute the next bound. If the Cholesky decomposition fails, one has found a \( k \) which violates the inequality constraint in the SDP. The tentative active set is then enlarged by one element and the maximization of \( \lambda_0 \) over the wavenumbers in the active set is run anew. If the new maximal \( \lambda_0 \) is larger by at least 0.1\% than the previous result, the new active set is accepted as such and Ra is increased to compute the next bound. If the fractional increase is less than 0.1\%, the newly added \( k \) is rejected as a false alarm and the old active set is used as the starting point for the computation of the bound at the next Ra. This rejection is a useful procedure because tolerances in the optimization together with round off errors accumulated during the Cholesky decomposition may lead the method to spuriously signal a violation of the constraint of positive semidefiniteness. The most straightforward way to distinguish a spurious from a warranted detection of violation is to check whether an enlarged set of wavenumbers leads to a more stringent constraint on \( \lambda_0 \). If it does not, the enlargement was unnecessary.

The most time consuming step in this entire method is the solution of the SDP. This was done with the Python interfaced version of the package cvxopt available from cvxopt.org, using either the internal solver of cvxopt or dsdp5. These codes implement central path methods which have the reputation of being the best choice for small to medium size problems. Resolutions of up to \( N = 512 \) were used for the results presented in this paper which are limited in Rayleigh number not because of an overwhelming computational burden, but because the SDP solvers failed to converge at large Ra. The SDP package was used as a black box which precluded a precise tracking of the problem, but round off issues are the most likely culprit. Ierley et al. report that they had to use a 96 digit floating point rep-
presentation to cover their interval of Ra in an implementation of the CDH method. The package used for the present work did not allow one to vary floating point types, so that the effect of the data type on convergence was not tested. The internal solver of cvxopt allowed to treat slightly larger Ra than dsdp5, and if both methods converged, they converged to the same result.

Even though it is enough to enforce \( \theta = 0 \) at the boundaries, it helped to require \( \partial_z^2 \theta = 0 \) as well. Again, both sets of boundary conditions lead to the same results if the SDP solver converges, but the extended boundary conditions allow one to reach higher Ra. The use of Chebychev polynomials is not the root of the convergence problems. For free slip boundaries, it is also convenient to choose \( \varphi_n = \sin(n \pi z) \) and an expansion of \( \theta \) in \( \sin(n \pi z) \) instead of Chebychev polynomials. This choice also leads to convergence problems at very much the same Ra.

Some relief is provided by an obvious modification of the method which consists in integrating by parts in eq. (12) in order to obtain

\[
\partial_t \langle \varphi_n \theta \rangle = -\langle (\partial_z \varphi_n) \theta \Delta_2 \phi \rangle - \langle (\partial_z \varphi_n) (\partial_z \theta) \rangle + \varphi_n(1) \langle \partial_z \theta \rangle_{A,z=1} - \varphi_n(0) \langle \partial_z \theta \rangle_{A,z=0} \tag{24}
\]

and to choose the test functions \( \varphi_n \) such that \( \partial_z \varphi_n = \delta(z-z_n) \) with the Chebychev collocation points defined in eq. (17). In order to preserve the symmetry about \( z = 1/2 \), one can express the test function at the boundaries as

\[
\varphi(0) = \varphi(\frac{1}{2}) + \int_{\frac{1}{2}}^0 \partial_z \varphi dz = \varphi(\frac{1}{2}) - \sum_{n=1}^{N/2} \lambda_n \tag{25}
\]

\[
\varphi(1) = \varphi(\frac{1}{2}) + \int_{\frac{1}{2}}^1 \partial_z \varphi dz = \varphi(\frac{1}{2}) + \sum_{n=N/2+1}^{N} \lambda_n \]

for \( \varphi(z) = \sum_{n=1}^{N} \lambda_n \varphi_n(z) \) with \( N \) even. We can therefore replace the functional \( G \) with \( G' \) defined as

\[
G'(\lambda_1...\lambda_N, \lambda_R, \theta) = -\sum_{n=1}^{N} \lambda_n \langle \delta(z-z_n) [\theta \Delta_2 \phi + \partial_z \theta] \rangle + \varphi(\frac{1}{2}) \langle \langle \partial_z \theta \rangle_{A,z=1} - \langle \partial_z \theta \rangle_{A,z=0} \rangle
\]

\[
+ \sum_{n=1}^{N/2} \lambda_n \langle \partial_z \theta \rangle_{A,z=0} + \sum_{n=N/2+1}^{N} \lambda_n \langle \partial_z \theta \rangle_{A,z=1} + \lambda_R \left[ \langle \theta \Delta_2 \phi \rangle + \langle \| \nabla \theta \|^2 \rangle \right] \tag{26}
\]
and we must obtain identical results if we replace $G$ with $G'$ in eq. (14). Because of the symmetry of the optimal test function, $\varphi(z) = -\varphi(1 - z)$ so that $\varphi(\frac{1}{2}) = 0$, and the second term in $G'$ disappears. $G'$ still looks more complicated than $G$ but does not contain second derivatives. As a result, the implementation using $G'$ has better convergence properties and is preferred for this reason.

Finally, rescaling $\lambda_0$ improves convergence. If the optimal $\lambda_0$ approximately equals $c Ra^\gamma$ with some constants $c$ and $\gamma$, it helps to use the variable $\lambda'_0 = \lambda_0 / (c Ra^\gamma)$ instead of $\lambda_0$ itself as an argument of the functional $G'$.

The central path methods also solve the dual problem. This part of the output allows one to compute the derivative of the optimal $\lambda_0$ with respect to problem parameters such as the wavenumbers $k$ (see example 5.13 in ref. [12]). This opens the possibility of using a gradient based method for maximizing $\lambda_0$ over $k$. This was done with a Newton-BFGS method. However, in order to run advantageously, this method needs derivatives with a higher precision than what the SDP solver sometimes provides. If the progress of Newton-BFGS was too slow, it was replaced by the gradient free Nelder-Mead optimization.

B. Relation with other methods

The background field or CDH method can be directly mapped onto the method of this section. It proceeds by using a different variable for the temperature variation, defined by $T(r, t) = \tau(z) + \theta'(r, t)$ where the background field $\tau$ is chosen such that $\tau(0) = 1, \tau(1) = 0$, and $\theta' = 0$ on the boundaries. It follows from the temperature equation (2) that

$$\partial_t \langle \frac{1}{2} \theta'^2 \rangle = -\langle \partial_z \theta' \partial_z \tau \rangle - \langle v_z \theta' \partial_z \tau \rangle - \langle |\nabla \theta'|^2 \rangle. \quad (27)$$

The CDH method now consists in finding $\tau(z), \lambda_0$ and $\lambda_R$ such that

$$-Z + \lambda_0 - \lambda_R \left( \langle \partial_z \theta' \partial_z \tau \rangle + \langle v_z \theta' \partial_z \tau \rangle + \langle |\nabla \theta'|^2 \rangle \right) \geq 0 \quad (28)$$

for all admissible $\theta'$ and $v_z$, in which case $\overline{Z} \leq \lambda_0$. This problem is not directly an SDP if $\tau$ appears quadratically in $Z$. It is then necessary to form a Schur complement in order to recover an optimization problem in SDP form\[11\]. This complicates a direct implementation of the CDH method compared with the method presented above. However, the bounds obtained from both methods must be identical, because after the identification $\varphi(z) =
\[ \sum \lambda_n \varphi_n(z) = \lambda_R (\tau - 1 + z) \]

one recognizes equations (28) and (14) to be the same. This also means that the boundary layer structure typical of optimal background fields will also appear in \( \varphi(z) \), and we also see that \( \varphi \) obeys \( \varphi(0) = \varphi(1) = 0 \).

As a further variation of the bounding problem, and in order to make contact with ref. 7, consider the test function \( \varphi_S \) with \( \varphi_S = 1 \) for \( z \leq l \) and \( \varphi_S = 0 \) for \( l < z \leq 1 \) for some \( l \) with \( 0 < l < 1 \). We then obtain

\[ \partial_t \langle \varphi_S \theta \rangle = - \int_0^l \langle \theta \Delta_2 \phi + \partial_z \theta \rangle_A dz - \langle \partial_z \theta \rangle_{A,z=0} \]

whose discretization is a suitable linear combination of eqs. (24). A bound for any time averaged \( Z \) in the form \( Z \leq \lambda_0 \) is then obtained if one finds \( \lambda_0 \), \( l \) and \( \lambda_R \) such that

\[ -Z + \lambda_0 - \int_0^l \langle \theta \Delta_2 \phi + \partial_z \theta \rangle_A dz - \langle \partial_z \theta \rangle_{A,z=0} + \lambda_R \left[ \langle \theta \Delta_2 \phi \rangle + \langle |\nabla \theta|^2 \rangle \right] \geq 0 \]

for all admissible \( \theta \) and \( \phi \). Seis\footnote{7} further restricts the problem to \( \lambda_R = 1 \) and shows how to solve it for general Prandtl number.

The functional \( G \) contains a linear combination of expressions which are the right hand sides of the time evolution equations of terms which are linear or quadratic in the flow variables \( \theta, \phi, \psi \). One could add linear combinations of the right hand sides of time evolution equations for higher moments, which would be equivalent to the auxiliary function approach\footnote{13,14}. This leads to an optimization problem with a constraint of the form that some polynomial must always be positive. An SDP can then only be formulated after relaxing this constraint to the less restrictive requirement that this polynomial is a sum of squares\footnote{13,14}.

C. Heat transport

We will now consider bounds on the heat transport as a validation of the method presented in this section. These bounds are obtained by setting \( Z = \langle |\nabla \theta|^2 \rangle \), or \( Z = \langle -\theta \Delta_2 \phi \rangle \) or \( Z = \langle -\partial_z \theta \rangle_{A,z=0} \). With all these three choices, \( \overline{Z} = \text{Nu} - 1 \), and the results obtained with the method described above are indeed the same. Fig. shows the optimal bound \( H \) on \( \text{Nu} - 1 \) found for both stress free and no slip boundaries. The distinction between the two boundary conditions appears only in the boundary conditions for the inverse bi-Laplacian in eq. (11).

For both boundary conditions, Ierley et al.\footnote{8} have obtained bounds from numerical optimization within the CDH method. Approximate expressions for those bounds are also
FIG. 1. The optimal upper bound \( H \) for the advective heat transport \( \text{Nu} - 1 \) as a function of \( Ra \) for stress free (circles) and no slip (squares) boundary conditions and infinite \( Pr \). The continuous lines show formulae obtained from fits in ref. 8, which are \( H = 0.101 \times Ra^{0.4} + 0.70965 \times Ra^{0.2} - 7.166 - 1 \) for free slip boundaries and \( H = 0.139 \times Ra^{1/3} - 1 \) for no slip boundaries.

FIG. 2. Wavenumbers \( k \) in the active set for the optimization of the bound \( H \) for free slip boundary conditions and infinite \( Pr \).

included in fig. These bounds conform with the analytical result that \( H \leq c_f Ra^{5/12} \) for free slip boundaries with some constant \( c_f \). Lower bounds are obtained if the number of elements in the active set is limited. The formula quoted in the caption of fig. is valid for up to two wavenumbers in the active set, which is appropriate for the range of \( Ra \) in fig. and which is a more accurate fit than the universally valid bound proportional to \( Ra^{5/12} \). For no slip boundaries, it is known that the CDH method cannot yield bounds better than proportional to \( Ra^{1/3}(\ln Ra)^{1/15} \). This agrees with the result of ref. apart from
FIG. 3. The optimal upper bound $H$ for the advective heat transport $\text{Nu} - 1$ as a function of $\text{Ra}$ for stress free boundaries and general $\text{Pr}$. The continuous line indicates the power law $0.055 \times (\text{Ra})^{1/2}$.

the virtually undetectable factor $(\ln \text{Ra})^{1/15}$.

Bounds obtained from the MHB method can be found in ref. 17 and in tabulated form in Vitanov’s doctoral thesis18. The numbers in the thesis match the results shown in fig. 1 to four digits accuracy.

Fig. 2 shows the wavenumbers included in the active set for the example of free slip boundaries. These are not exactly the same as those given in the analogous figure 12b of ref. 8 which shows an additional wavenumber at $\text{Ra} > 10^9$. This difference simply comes from the tolerances set in the automated search of the wavenumbers. The additional wavenumber for $\text{Ra}$ above $10^9$ does increase the bound $H$, but by less than 0.1% which is why it was rejected and does not appear in fig. 2.

IV. BOUNDS ON HEAT TRANSPORT AT GENERAL PRANDTL NUMBER

For finite $\text{Pr}$, one has to return to the general equations (5) and (6). The equations of evolution for $\langle \theta \rangle_A$ and $\langle \frac{1}{2} \theta^2 \rangle$, equations (9) and (8) remain unchanged, but the dot product of the momentum equation (11) with $\mathbf{v}$, averaged over the entire volume, now yields the additional non trivial information in eq. (7) that

$$\partial_t \langle \frac{1}{2} \mathbf{v} \rangle = -\text{PrRa} \langle \theta \Delta \Phi \rangle - \text{Pr} \langle \lvert (\hat{z} \times \nabla) \nabla^2 \phi \rvert^2 \rangle - \text{Pr} D_{np}$$

(31)
FIG. 4. Wavenumbers $k$ in the active set for the optimization of the bound $H$ for free slip boundary conditions and general Pr.

with the toroidal dissipation

$$D_{np} = \langle |\nabla \partial_x \psi|^2 + |\nabla \partial_y \psi|^2 \rangle.$$  \hspace{1cm} (32)

The subscript stands for non poloidal, because if periodic boundary conditions are imposed on $\psi$, this term has to include not only the dissipation due to the toroidal field but also the dissipation due to a horizontal mean flow\(^\text{19}\). Since $D_{np} \geq 0$, it will be convenient to introduce a new variable $d$ defined by $d^2 = D_{np}$.

We can now follow the same line of thought as in the previous section and construct a functional $F$ as

$$F(\lambda_1...\lambda_N, \lambda_R, \lambda_E, \theta, \phi, d) = \sum_{n=1}^{N} \lambda_n \langle \varphi_n \left[ \partial_z (\theta \Delta^2 \phi) + \partial_z^2 \theta \right] \rangle + \lambda_R \left[ \langle \theta \Delta^2 \phi \rangle + \langle |\nabla \theta|^2 \rangle \right]$$

$$+ \lambda_E \left[ Ra \langle \theta \Delta^2 \phi \rangle + \langle |(\widehat{\mathbf{z}} \times \nabla) \nabla^2 \phi|^2 \rangle \right] + \lambda_E d^2$$

and conclude that if we know $\lambda_0, \lambda_1...\lambda_N, \lambda_R, \lambda_E$ such that

$$- Z + \lambda_0 + F(\lambda_1...\lambda_N, \lambda_R, \lambda_E, \theta, \phi, d) \geq 0$$  \hspace{1cm} (34)

for all admissible $\theta, \phi$ and all $d$, we get the estimate $Z \leq \lambda_0$. The functional $F$ has to include both $\theta$ and $\phi$ as independent arguments because the relation (11) no longer holds for finite Pr. There is also an additional coefficient $\lambda_E$ which has to be positive in order to satisfy the inequality (34) for all $d$.

The bounding method was numerically implemented for stress free boundaries using identical expansions for $\theta$ and $\phi$ into Chebychev polynomials and Fourier series, and using
the same test functions $\varphi_n$ as for infinite Pr in the previous section. The optimizing fields $\theta$ and $\phi$ again have symmetry, which was exploited in the calculations with high resolutions. When expanded in $T_n(z) = T_n(2z - 1)$, the Fourier components of both $\theta$ and $\phi$ contain only terms with even $n$ for $k > 0$. There is no contribution to $\phi$ with $k = 0$, and the zero wavenumber contribution to $\theta$ contains only terms with odd $n$. Expressed differently, if $\theta = \sum_j \hat{\theta}_{k_x,j} \hat{\theta}_{k_y,j} e^{i(k_x x + k_y y)}$ and $k^2 = k_x^2 + k_y^2$, then $\hat{\theta}_{k_x,j} = \hat{\theta}_{k_x,j} (1 - z)$ and $\hat{\theta}_{0,0} (z) = -\hat{\theta}_{0,0} (1 - z)$, and likewise for the poloidal field. The optimal $\varphi(z)$ has the same symmetry as for infinite Pr.

Bounds $H$ for $\text{Nu} - 1$ are obtained by setting $Z$ to either of the following expressions: $\langle |\nabla \theta|^2 \rangle$, $\langle -\theta \Delta^2 \phi \rangle$, or $\langle -\partial_z \theta \rangle_{A,z=0}$. All three options yield identical results and they agree to four digits accuracy with values listed in Vitanov’s thesis\textsuperscript{18}. The result is shown in fig. 3. The bounds obey approximately $H = 0.055 \times \text{Ra}^{1/2}$. The active set now contains more wavenumbers, as shown in fig. 4.

V. BOUNDS ON THE VELOCITY FIELD

The previous sections investigated bounds on heat transport or thermal dissipation, a quantity obtainable from the temperature field alone. The present section deals with the velocity field, which is characterized first and foremost by its energy. Rewriting eq. (7), the dissipation of the velocity field is given by

$$\sum_{ij} \langle (\partial_j v_i)^2 \rangle = \text{Ra}(\text{Nu} - 1)$$

(35)

so that a bound on $\text{Nu} - 1$ also bounds the kinetic dissipation. We can now invoke Poincaré’s inequality, which states that $\int_0^1 (\partial_z f)^2 dz \geq \eta \int_0^1 f^2 dz$ for any function $f(z)$ defined on the interval $0 \leq z \leq 1$, where $\eta$ is the smallest eigenvalue of the Laplace equation $-\partial_z^2 g = \eta g$, if $g$ and $f$ obey the same boundary conditions. For Dirichlet boundaries, $\eta = \pi^2$. Neumann boundary conditions do not uniquely select a solution. If $f$ obeys $\int_0^1 f(z)dz = 0$ in addition to the Neumann conditions, one has again $\eta = \pi^2$. We now also use the fact that the total dissipation is greater than the dissipation due to the poloidal velocity field $\mathbf{v}_P$ alone, and that all components in $\mathbf{v}_P = \partial_z \partial_x \phi \hat{x} + \partial_z \partial_y \phi \hat{y} - \Delta_2 \phi \hat{z}$ either obey Dirichlet conditions in $z$, and
FIG. 5. The optimal upper bound $E$ for the poloidal kinetic energy as a function of $Ra$ at infinite Pr for stress free (circles) and no slip (squares) boundary conditions as well as for general Pr and free slip boundaries (plus signs). The continuous line indicates the power law $0.00147 \times Ra^{4/3}$.

or satisfy Neumann conditions and their integral over $z$ is zero:

$$\sum_{ij} \langle (\partial_j v_i) \rangle^2 \geq \sum_{ij} \langle (\partial_j v_{P,i}) \rangle^2 \geq \langle (\partial_z v_{P,x})^2 + (\partial_z v_{P,y})^2 + (\partial_z v_{P,z})^2 \rangle \geq \pi^2 \left( \langle v_{P,x}^2 \rangle + \langle v_{P,y}^2 \rangle + \langle v_{P,z}^2 \rangle \right)$$

(36)

If $H$ is an upper bound for $Nu - 1$, the poloidal energy is thus bounded as

$$RaH \geq 2\pi^2 E_{pol}.$$  

(37)

For infinite Pr, the velocity field is purely poloidal and poloidal and total energies are identical. For finite Pr, the toroidal field and a possible mean flow also contribute to the kinetic energy, but they do not appear in the constraints employed in the formulation of the optimization problem in section [V]. We therefore cannot obtain any additional information about the total energy, we can only hope to find tight bounds on the poloidal energy with the technique described above. The bound (37) derives solely from the energy budget (35) and the definitions of kinetic dissipation and energy. We expect to find tighter bounds by solving the full optimization problem.

Setting $Z = \langle \frac{1}{2} |\nabla \times \nabla \times (\phi \hat{z})|^2 \rangle$ and repeating the same computations as in the previous section yields bounds $E$ on the poloidal energy. Figure 5 shows the bounds as a function of $Ra$ for different cases and table I summarizes the results by fitting power laws through...
FIG. 6. The optimal upper bound $E$ for the poloidal kinetic energy as a function of Ra at infinite Pr and stress free boundaries. The continuous line shows the function $0.033 \times RaH$, where $H$ is the upper bound on the advective heat transport from fig. [1].

| Condition                | $H$         | $E$            | $RaH/(2\pi^2)$ |
|--------------------------|-------------|----------------|----------------|
| infinite Pr, free slip   | $0.033 \times RaH$ | $0.05066 \times RaH$ |
| infinite Pr, no slip     | $0.139 \times Ra^{1/3}$ | $0.00147 \times Ra^{4/3}$ | $0.00704 \times Ra^{4/3}$ |
| general Pr, free slip    | $0.055 \times Ra^{1/2}$ | $0.00106 \times Ra^{3/2}$ | $0.002786 \times Ra^{3/2}$ |

TABLE I. Fitted dependencies on Ra of $H$ and $E$, the optimal upper bounds on $Nu - 1$ and $E_{pol}$. The table also lists $RaH/(2\pi^2)$ for comparison with $E$.

the points at high Ra. A power law fit is not quite satisfactory yet at infinite Pr for free slip boundaries at the Ra accessed in these computations. Fig[3] presents for this reason an alternative point of view in which $E$ is directly compared with $RaH$.

In all cases, the full optimization problem improves prefactors compared with the direct estimate $RaH/(2\pi^2)$, but not the exponent in the power laws or the functional form of the Rayleigh number dependence. The prefactor improves by a factor ranging from 1.5 to 4.8.

There is an interesting curiosity about the bounds for free slip boundaries. The bounds for infinite and general Pr agree to better than within 1% as long as there is only one wavenumber in the active set. The difference between the two cases becomes obvious only once the active set contains more than one wavenumber.

Some of the fitted power laws in table[1] can be compared with data from direct numerical simulations. The comparison is scarce in the case of infinite Pr and no slip boundaries.
Numerical simulations did not go to high enough Rayleigh numbers to be definitive about asymptotic scalings. Travis et al.\textsuperscript{20} found $\text{Nu} = 0.406 \times \text{Ra}^{0.284}$, but Sotin and Labrosse\textsuperscript{21} argue that this scaling only holds for time independent convection, and that $\text{Nu} = 0.517 \times \text{Ra}^{0.269}$ once time dependence sets in. However, their simulations were restricted to $\text{Ra} < 10^{7}$. Theoretical arguments put forward by Grossmann and Lohse\textsuperscript{22} lead to $\text{Nu} \propto \text{Ra}^{1/3}$ and $E_{\text{pol}} \propto \text{Ra}^{4/3}$. These exponents are the same as those listed in table\textsuperscript{1} for the bounds.

More results are available for infinite Pr and free slip boundaries. In that case, Christensen\textsuperscript{23} finds numerically $\text{Nu} = 0.196 \times \text{Ra}^{1/3}$ and Pandey et al.\textsuperscript{24} obtain $\text{Nu} = 0.23 \times \text{Ra}^{0.32}$. These relations depend to some extent on the interval of $\text{Ra}$ included in the fit (typically $10^{5} - 10^{8}$ for ref. \textsuperscript{24} and up to $10^{11}$ for ref. \textsuperscript{23}) and also the aspect ratio of the computational volume (which was actually 2D in Christensen’s case), but the point is that there is roughly a factor of up to 2 between the bound $H$ and the numerical results for $\text{Ra} < 10^{10}$ with a widening gap if the quoted exponents persist to higher $\text{Ra}$. Pandey et al.\textsuperscript{24} also give the kinetic energy for free slip boundaries at infinite Pr in a box of size $2\sqrt{2} : 2\sqrt{2} : 1$ as $0.02 \times \text{Ra}^{6/5}$ for $10^{5} \leq \text{Ra} \leq 10^{8}$. This is nearly two orders of magnitude below the bound even at $\text{Ra} = 10^{8}$, and the discrepancy is worsening with increasing $\text{Ra}$ due to the discrepancy in the exponents. The kinetic energy deduced from the characteristic surface velocity obtained by Jarvis and Peltier\textsuperscript{25} varies as $\text{Ra}^{1.29}$. While closer to 1.4, this exponent is still much smaller than the one appearing in the bound.

At finite Pr, various simulations have found kinetic energy approximately proportional to $\text{Ra}$, so that in an all cases, the bounds for $E_{\text{pol}}$ severely overestimate the kinetic energy.

Another apparent overestimate is the bound for $\text{Nu}$ at general Pr. There are arguments\textsuperscript{26} in favor of a scaling in the form $\text{Nu} \propto \text{Ra}^{1/2}$ at large $\text{Ra}$, the so called ultimate regime. However, there is as of yet no unequivocal experimental or numerical observation of the ultimate regime and the exponents $\gamma$ in $\text{Nu} \propto \text{Ra}^{\gamma}$ obtained from fits to observational data are less than 1/2. Their precise value depends\textsuperscript{27} on Pr and $\text{Ra}$, but $\gamma$ is often found to be around 1/3. The fact that no bound better than $\text{Nu} - 1 = c\text{Ra}^{1/2}$ with some constant $c$ is known for 3D convection is sometimes seen as an indication that the ultimate regime will eventually be observed at high enough $\text{Ra}$.

A simple argument in favor of $\text{Nu} \propto \text{Ra}^{1/2}$ is dimensional analysis. This scaling must hold if the heat transport is independent of molecular diffusivities. If one applies the same argument to kinetic energy, one concludes that $g\alpha \Delta T \text{h}$ is the only acceptable combination of
FIG. 7. The optimal upper bound $D$ for the non poloidal dissipation $D_{np}$ a function of $Ra$ for general $Pr$ and stress free boundaries. The continuous line indicates the power law $0.021 \times Ra^{3/2}$.

problem parameters other than molecular diffusivities with dimensions of velocity squared, which translates into a kinetic energy proportional to $Ra$. It is therefore very likely that the scaling in $Ra^{3/2}$ shown by the bound will never be observed for the poloidal kinetic energy, not even in a surmised ultimate regime.

A scenario which generates large upper bounds is the existence of a stationary solution with high kinetic energy which is unstable and therefore never observed in an actual time evolution of the flow, but which prevents any bound from approaching the observed kinetic energy of the flow. It is at present not possible to tell whether this scenario is realized. The optimal flow field of the SDP is not a candidate for this possible stationary flow field. The optimal flow field contains only a few wavenumbers and not their harmonics or other mixtures, as a solution of the Navier-Stokes equation would necessarily do.

Finally, while it is not possible to bound the energy contained in the non poloidal components, it is possible to bound the dissipation due to them, $D_{np}$. Again, the energy budget immediately provides us with a bound:

$$D_{np} \leq \sum_{ij} \langle (\partial_j v_i)^2 \rangle \leq Ra(Nu - 1) \leq RaH. \quad (38)$$

With the data in table II we conclude that $D_{np} \leq 0.055 \times Ra^{3/2}$. Setting $Z = D_{np}$ and going through the whole optimization procedure leads to a better bound, $D_{np} \leq 0.021 \times Ra^{3/2}$, shown in fig. 7, but the improvement is once again only in the prefactor, not in the exponent.

In an effort to improve any of these bounds, one may think of having recourse of the maximum principle, which guarantees that, possibly after transients due to initial conditions,
the temperature anywhere in the fluid must lie in between the temperatures of top and bottom boundaries, $0 \leq T = \theta + 1 - z \leq 1$. This means that the inequality (14) does not need to hold for any $\theta$ satisfying the boundary conditions, it is enough if it holds for every $\theta$ satisfying the boundary conditions and the maximum principle.

The inequality (19) decouples in $k$. It contains only quadratic terms for $k \neq 0$. In order to violate this inequality in one of the matrix blocks with $k \neq 0$, it is necessary that some block possesses at least one negative eigenvalue. This condition is independent of whether the admitted fields $\theta$ obey the maximum principle or not. For $k = 0$ on the other hand, the inequality (19) or (14) also contains linear terms and there is a non zero $\theta$ which minimizes the left hand side of (14). The minimizing $\theta$ was computed for the optimal $\lambda$’s and was found to conform to the maximum principle in all cases. It would therefore lead to no improvement to explicitly impose this condition during the optimization process.

VI. CONCLUSION

This paper presented a new method to numerically compute upper bounds for heat transport, dissipation, and poloidal energy in Rayleigh-Bénard convection both for infinite and general Prandtl number. The center piece of the method is a semidefinite program, which is numerically convenient to implement, but formally equivalent to the background field method.

The SDP can be solved with existing numerical libraries. While it is convenient to use an SDP solver as part of the overall procedure, it is not necessarily efficient. The obvious alternative is to solve Euler-Lagrange equations. The disadvantage of this option is that the Euler-Lagrange equations have many stationary points, only one of which is the solution of the SDP which is a convex optimization problem. On the other hand, finding optimal bounds amounts to finding a saddle point, with a minimization over the coefficients $\lambda$ and a maximization over the wavenumbers in the active set. These two optimizations have to be run separately and sequentially if an SDP solver based on central path methods is used, but both can be combined into a single root search if Euler-Lagrange equations are solved.

Once dissipation is bound, the mere definitions of dissipation and energy lead to a bound on energy. Including the additional constraints employed in optimum theory as it is used nowadays leads to tighter bounds, but only through improved prefactors, not through smaller
exponents in power laws or new functional dependencies. It remains to be seen which additional constraints lead to further improvement of the upper bounds. The maximum principle for the temperature field can be of no help as it is already obeyed by the optimizing fields in the method presented here.

The exponent found for the bound on poloidal energy for general Prandtl numbers is not plausible for a tight bound. Either there exist stationary unstable flows which prevent better bounds, or the exponent can be improved by including additional constraints derived from the Navier-Stokes equations into the optimization process. If additional constraints have such an effect on the bound for the poloidal energy, they may also reduce the exponent of the known upper bound for the Nusselt number. This bound is compatible with the expected, but as of yet unobserved, ultimate regime of convection. The existence of this regime would be contradicted if the exponent in the bound for the Nusselt number could be reduced.
