PRELIMINARY EVALUATION OF FENUGREEK (**TRIGONELLA FOENUM-GRAECUM**) SEED GUM AS A POTENTIAL PREBIOTIC FOR GROWING RABBITS IN TUNISIA: EFFECTS ON **IN VIVO** Faecal Digestibility and **IN VITRO** Fermentation

ZEMZMI J.*, RÓDENAS L., BLAS E., ABDOULI H., NAJAR T., PASCUAL J.J.*

Abstract: This study aims to determine the effect of dietary inclusion of fenugreek seed gum (FSG), rich in galactomannans, on nutrient apparent digestibility and caecal environment, as well as on **in vitro** caecal fermentation of Tunisian growing rabbits. Three experimental diets were formulated, including 0, 0.25 and 0.5% of FSG (FSG0, FSG0.25 and FSG0.5, respectively) for the **in vivo** trial and 0, 0.125, 0.25, 0.5 and 100% of FSG (FSG0, FSG0.125, FSG0.25, FSG0.5 and FSG100, respectively) for the **in vitro** trial. In the **in vivo** trial, 45 weaned rabbits 31 d old (15 per treatment) were housed in individual cages until 94 d of age. Apparent digestibility coefficients were determined at two ages, from 38 to 41 and from 56 to 59 d old, and caecal traits were recorded after slaughtering. In the **in vitro** trial, the five experimental diets were incubated with a rabbit caecal inoculum. Gas production was measured and modelled until 72 h and the fermentation traits were measured. Apparent faecal digestibility coefficients of main nutrients and main caecal environment traits were not significantly affected by the dietary inclusion of FSG (P>0.05). However, animals fed with FSG showed lower caecal pH (–0.15; P<0.05) values. Regarding the **in vitro** fermentation, FSG100 increased asymptotic gas production (+11.25, P<0.001), sharpness of the switching characteristic of the profile (+1.98, P<0.001) and the maximum substrate degradation rate (RM) (+0.188, P<0.001), but decreasing the time after incubation at which half of the asymptotic amount of gas has been formed (–5.86, P<0.001) and at which RM occurs (–4.53, P<0.01). Likewise, FSG100 significantly decreased caecal pH (–1.035, P<0.001), lactic acid (–9.51, P<0.069) and N-NH$_3$ concentrations (–12.81, P<0.001). Meanwhile, it increased the total volatile fatty acids (VFA) production (+43.15, P<0.001). Gradual dietary inclusion of FSG from 0 to 0.5% only significantly increased total VFA production in the caecum (+100 mmol/L per percentage point of FSG inclusion; P<0.05). In conclusion, FSG is highly and rapidly **in vitro** fermented by rabbit caecal bacteria. However, dietary inclusion of FSG up to 0.5%, might be insufficient to affect the apparent digestibility and fermentation profile of growing rabbits to a great extent.

Key Words: rabbit, **in vivo**, **in vitro**, fenugreek seed gum, faecal digestibility, caecal fermentation.

INTRODUCTION

One of the main limitations and concerns in rabbit farming is the frequency of digestive disorders, especially after weaning. Rosell et al. (2009) reported that 54.1% of the urgent visits to commercial rabbit farms in Spain and Portugal during 1997 to 2007 were due to digestive tract diseases. Under these circumstances, increasing the dietary soluble fibre content has shown to be an effective strategy to improve the integrity of the intestinal mucosa and modulate the intestinal microbiota of rabbits (Gómez-Conde et al., 2007, 2009; Trocino et al., 2013a). Thus, the inclusion of 20 to
30% of beet pulp (rich in soluble fibre) promotes caecal fermentation, promoting butyrate proportion, which is usually related to a reduced mortality associated with digestive disorders (Martínez-Vallespin et al., 2011, 2013). An alternative to a high inclusion of soluble fibre-rich raw materials, which also increases other fibrous fractions or could increase the amount of protein linked to fibre, is the direct inclusion of a small amount of an isolated soluble fibre so that, acting as a prebiotic, it could allow us to obtain these same effects (Falcão-e-Cunha et al., 2007). To this end, some works (Bónai et al., 2010; Volek and Marounek, 2011) have evaluated the dietary inclusion of inulin-type fructans from chicory extracts, which seems to affect caecal fermentative activity in growing rabbits, but without relevant positive effects on the growing performance and digestive health of the animals. In other works, the inclusion of mannan-oligosaccharides (Bovera et al., 2010) afforded a reduction in rabbit mortality and an improvement in growth performance, whereas supplementation with gluco-oligosaccharides (Gidenne, 1995) had no effect on the caecal fermentation pattern and even a negative effect on morbidity and mortality. Lack of consistency in the results obtained with prebiotics could be explained by differences in the trial conditions, the nature of the prebiotic used or the amount of prebiotic added to feed (Falcão-e-Cunha et al., 2007).

Trigonella foenum-graecum, known as fenugreek, is an annual herb of the Leguminosae family, originating in the Near East and widely produced in India and Northern Africa as a spice and forage crop. In Tunisia, fenugreek is widely cultivated in the North-western and North-eastern regions. However, despite its potential interest as forage, fenugreek use remains limited, perhaps because some works (Bartley et al., 1981; Sewell et al., 1999; Korman et al., 2001; Mazza et al., 2002) have associated its intake with an unpleasant taste in cattle’s meat and milk, as well as a strong odour in human sweat and urine. Fenugreek seeds contain 30.6 and 20.6% of soluble and insoluble dietary fibre, respectively (Naidu et al., 2011). The main component of its soluble fibre is a galactomannan, which is a polysaccharide structurally composed of a main chain of b-(1,4)-linked d-mannopyranose, where 83.3% of the main chain is substituted at C-6 with a single residue of a-(1,6)-D-galactopyranose (Jiang et al., 2007). Fenugreek seed gum (FSG), which corresponds to the soluble fibre fraction, is obtained by aqueous extraction followed by ethanol precipitation (Zemzmi et al., 2017), which eliminates the odour problems of the product. This FSG contains 63.5% of this galactomannan, which can be a potential prebiotic due to its resistance to acid and pancreatic digestion and its high fermentability (Majeed et al., 2018).

As an initial approach, the aim of this study was to determine the effect of dietary inclusion of FSG on the nutrient apparent digestibility and caecal environment of growing rabbits, as well as on in vitro caecal fermentation, to evaluate the potential of this product as a prebiotic for Tunisian growing rabbits.

**MATERIALS AND METHODS**

**Galactomannan extraction**

Following the recommendations of Zemzmi et al. (2017), fenugreek seeds were ground to pass a 2 mm diameter mesh, defatted in hexane-isopropanol (3/2, v/v), extracted in distilled water for 24 h and precipitated with ethanol 95°. Then, the FSG extracted was washed with acetone and finally freeze-dried and ground into a white powder.

**Diets**

Experimental diets were obtained using as basis a commercial feed, including as main ingredients alfalfa hay, wheat bran, soybean meal and barley grain. Using this basal diet, three experimental diets were formulated and pelleted including 0, 0.25 and 0.5% of FSG (FSG0, FSG0.25 and FSG0.5, respectively) for the in vivo trial and 0, 0.125, 0.25, 0.5 and 100% of FSG (FSG0, FSG0.125, FSG0.25, FSG0.5 and FSG100, respectively) for the in vitro trial. Chemical composition of the experimental diets is presented in Table 1.

**Animals and housing**

The trial was carried out at the experimental farm of the Higher School of Agriculture of Mateur (Carthage University, Tunisia Republic). The experimental procedure was carried out following the recommendations of the European Group
Fenugreek seed gum as a prebiotic for rabbits

Forty-five weaned crossbreed rabbits (New Zealand White × Californian), at 31 d of age, were randomly assigned to one of the three treatments (15 rabbits/group). Animals were housed in individual cages (78×46×23 cm) from 31 to 94 d of age, equipped with a feeder and a drinker to provide free access to feed and water. The lighting schedule was 16 h light/8 h dark throughout the experimental trial. Weaned rabbits had a similar live weight at the beginning of the trial (552.12±12.72, 545±13.17 and 550.13±12.73 for FSG₀, FSG₀.25 and FSG₀.5, respectively). Mortality and morbidity were controlled daily. Ten non-morbid rabbits per treatment with a similar live weight were used to determine the individual apparent faecal digestibility coefficients for dry matter (DM), organic matter, crude protein (CP), neutral detergent fibre (NDF) and acid detergent fibre (ADF). Apparent digestibility coefficients for ether extract (EE), total dietary fibre (TDF) and soluble fibre (SF) were determined from the pool of faeces from each treatment. The digestibility trial was performed at two ages using the same group of animals, from 38 to 41 and from 56 to 59 d of age. Following the recommendations of Perez et al. (1995), faeces and feed intake were controlled for 4 d, by covering the bottom of the cage with perforated plastic bags to eliminate urine. Faeces were stored in identified sealed plastic bags and frozen at −20°C until analysis. At 94 d of age, all animals were slaughtered between 8:00 and 10:00 am. After skin removal, pH value of caecal content was measured and an aliquot of caecal content was placed in a 45 mL plastic tube with 20 µL of 10% HgCl₂ to stop caecal fermentation and stored at –20°C for subsequent determination of VFA profile, N-NH₃ and lactic acid content.

**In vitro fermentation**

The gas production kinetics of FSG diets were determined in an in vitro fermentation trial. Two New Zealand 70 d old rabbits were fasted overnight, with free access to water, before their slaughter between 8:00 and 10:00 am. Caecal contents from both animals were collected, mixed and stirred for few minutes. Finally, 100 mL of the mixed caecal content were homogenised under CO₂ bubbling in 400 mL of solution A (including 10 g/L KH₂PO₄, 0.5 g/L MgSO₄·7H₂O, 0.5 g/L NaCl and 0.1 g/L CaCl₂·2H₂O) and 8 mL of solution B (including 15 g/L Na₂CO₃ and 0.25 g Cysteine-HCl) and the inoculum solution obtained was filtered through six layers of cheesecloth (Marten and Barnes, 1980). Propylene sterile syringes of 60 mL were used for the incubation. Twenty mL of inoculum solution was included in each syringe with 200 mg of treatment (FSG₀, FSG₀.125, FSG₀.25, FSG₀.5 and FSG₁₀₀). A total of 24 syringes were used in this trial, four syringes for each of the five treatments, as well as another four for the blanks (inoculum solution without substrate). Syringes were quickly placed in an oven and incubated at 39°C for 72 h. Gas production

**Table 1: Chemical composition of the experimental diets (% dry matter), including different levels of fenugreek seed gum (FSG), used both in the in vivo and in vitro fermentation trials.**

|                      | FSG₀ | FSG₀.25 | FSG₀.5 | FSG₀ | FSG₀.125 | FSG₀.25 | FSG₀.5 | FSG₁₀₀ |

was recorded at 1, 3, 6, 8, 12, 18, 22, 30, 36, 42, 48, 54, 60, 66, and 72 h post inoculation. At the end of incubation (72 h), 0.1 mL of \( \text{HgCl}_2 \) 10% was added to each syringe to stop fermentation. After direct measurement of pH, syringe content was transferred to 45 mL plastic tubes and centrifuged at 3000 rpm for 10 min. Supernatant was transferred in another tube and stored at 4°C to determine total VFA, N-NH\(_3\), and lactic acid concentration, as well as the VFA profile. Gas production values at each measurement time were corrected for gas produced at this time by the corresponding blanks. Gas production data were fitted to the monophasic model described by Groot et al. (1996):

\[
G = \frac{A}{1 + \left(\frac{B}{t}\right)^c}
\]

In this equation, \( G \) (mL g\(^{-1}\) DM) is the amount of gas produced per gram of DM incubated, at time \( t \) after incubation; \( A \) (mL g\(^{-1}\) DM) is the asymptotic gas production; \( B \) (h) is the time after incubation at which half of the asymptotic amount of gas has been formed; and \( C \) is the constant determining the sharpness of the switching characteristic of the profile. Maximum substrate degradation rate (\( R_M \)) and the time after the start of the incubation at which \( R_M \) occurs (\( t_{RM} \)) were also calculated as:

\[
t_{RM} = B(C-1)^{1/c} \rightarrow R_M = \frac{Ct_{RM}^{(C-1)}}{B^c+t_{RM}^c}
\]

**Chemical analysis**

The AOAC (2002) methods were used for DM (934.01), ash (942.05), CP (990.03, Dumas method, CN628 Elemental Analyzer, LECO, St. Joseph, MI, USA) and EE (920.39, with acid-hydrolysis of samples prior to the extraction). Starch content was determined according to Batey (1982) in a two-step enzymatic procedure with solubilisation and hydrolysis to maltodextrins with thermo-stable \( \alpha \)-amylase followed by complete hydrolysis with amyloglucosidase (both enzymes from Sigma-Aldrich, Steinheim, Germany), and the resulting D-glucose was measured by the hexokinase/glucose-6-phosphate dehydrogenase/NADP system (kit D-glucose-HK Megazyme Int. Ireland Ltd., Wicklow, Ireland). The TDF content was determined by a gravimetric-enzymatic method, procedure 991.43 of Van Soest et al. (1991), with \( \alpha \)-amylase, protease and amyloglucosidase treatments (Megazyme TDF R.30.K-TDFR-100A/200A), correcting for ash and CP. The NDF, ADF and lignin detergent fibre (ADL) fractions were analysed sequentially according to Mertens (2002), AOAC procedure 973.18 (2002) and Robertson and Van Soest (1981), respectively, with a thermo-stable \( \alpha \)-amylase pre-treatment and expressed exclusive of residual ash, using a nylon filter bag system (Ankom, Macedon, NY, USA). The SF content was determined as proposed by Van Soest et al. (1991), by subtracting the NDF corrected for CP from the TDF. Determination of VFA was based on the method described by Jouany (1982). Samples were filtered through 0.45 µm cellulose syringe filters. Next, 100 µL of an internal standard solution (0.4 g of 4-methylvaleric acid diluted in 100 mL of deionised water) and 0.1 mL of a preservative (5% \( \text{H}_3\text{PO}_4 \) and 1% \( \text{HgCl}_2 \) in deionised water) were added to 0.9 mL of filtrate. One µL from each sample was injected into a gas chromatograph (Fisons 8000 series, Milan, Italy) equipped with a split/split less injector and FID detector. The separation of VFA was done in a DB-FFAP capillary column (30 m×0.25 mm×0.25 µm of film thickness, J&W Scientific, Folson, CA, USA). The carrier gas was \( \text{N}_2 \) at a constant pressure of 120 kPa. Injector and detector temperatures were set at 200°C and 245°C respectively. The initial oven temperature was set at 110°C held for 5 min and increased to 230°C at 8.5°C/min and finally maintained at that temperature for 10 min. Finally, VFA were identified by comparing their retention times with a standard (46975-U from Supelco®), Bellefonte, PA, USA). N-NH\(_3\) concentration was determined using the nesslerisation spectrophotometric method adapted by Koroleff (1966). The VFA and N-NH\(_3\) concentrations were expressed as mmol/L of the liquid phase of caecal digesta. Lactic acid was determined according to the method of Borschchevskaya et al. (2016), where an aliquot of the samples was diluted 20 times with deionised water, 50 µL from the dilution was added to 2 mL of a 0.2% solution of \( \text{FeCl}_3 \), the mixture was stirred and absorbance was measured at 390 nm against a reference solution (2 mL of a 0.2% \( \text{FeCl}_3 \)). Colour solution was stable for 15 min. All *in vitro* traits values were corrected by their corresponding blanks.
Statistical analysis

All the traits in this work were statistically analysed with a General Linear Model (GLM) procedure from SAS (2009). For the digestibility traits, the model included the effect of FSG inclusion (0, 0.25 and 0.5%), the age (38 and 56 d) and their interaction as main effects. However, for the caecal environment and in vitro traits, the model only included the effect of FSG inclusion (0, 0.25 and 0.5%, or 0, 0.125, 0.25 and 0.5%, respectively) as main effect. An orthogonal contrast to evaluate the effect of FSG inclusion \([\text{FSG}_0 - (\text{FSG}_{0.25} + \text{FSG}_{0.5}) / 2]\) was performed for digestibility and caecal traits, while possible linear effect of FSG inclusion (from 0 to 0.5%) was evaluated for the in vitro traits.

RESULTS

All animals were perfectly adapted to the experimental diets and no morbidity or mortality problems were recorded throughout the growing period. No significant differences were observed for the final body weights at 94 d of age, which were 2360±32, 2428±32 and 2376±32 for FSG\(_0\), FSG\(_{0.25}\) and FSG\(_{0.5}\), respectively. During the digestibility trial, daily feed intake obviously increased with the age of the growing rabbits (+28% from 38 to 56 d; \(P<0.001\)), but was not affected by the inclusion level of FSG in the diet (Table 2). Apparent faecal digestibility coefficients (d) of main nutrients were not significantly affected by the dietary inclusion of FSG. However, dNDF and dADF values at 56 d were significantly higher than those observed at 38 d of age (+0.049 and +0.048 percentage points, respectively; \(P<0.05\)), which could explain the higher dDM with the age observed (+0.021; \(P=0.051\)). No significant interaction was observed between the inclusion of FSG and age during the digestibility trial. The effect of dietary inclusion of FSG on the caecal traits is presented in Table 3. No significant effect of the dietary inclusion of FSG on any of the traits related to the caecal environment was observed. However, animals fed with FSG showed lower caecal pH (–0.15; \(P=0.037\)) and slightly higher caproic acid concentration in the caecum (+0.48%; \(P=0.093\)) than those fed with FSG\(_0\). Table 4 shows the effect of dietary inclusion of FSG on the gas production parameters estimated throughout incubation and the in vitro traits controlled at the end of this incubation. In comparison to the experimental diets, pure FSG (FSG\(_{100}\)) significantly affected the main gas kinetic parameters (Figure 1a), increasing A, C and \(R_M\) traits, but decreasing B and \(t_B\) traits (\(P<0.001\)). However, gradual dietary inclusion of FSG (from 0 to 0.5%) had no effect on any of these kinetic parameters (Figure 1b). Similarly, FSG\(_{100}\) significantly decreased caecal pH and total VFA production, as well as lactic acid and N-NH\(_3\) concentrations compared to the values observed with the experimental diets (\(P<0.001\)). Finally, gradual dietary inclusion of FSG

![Figure 1: Evolution of gas production during the in vitro incubation of fenugreek seed gum (FSG) and the experimental diets with caecal inocula: (a) Comparison of pure FSG (FSG\(_{100}\)) with the basal diet (FSG\(_0\)); (b) Comparison of the four experimental diets including 0, 0.125, 0.25 and 0.5% of FSG (FSG\(_0\), FSG\(_{0.125}\), FSG\(_{0.25}\) and FSG\(_{0.5}\), respectively). Curves fitted to the monophasic model of Groot et al., 1996 [\(G_t = A/(1+(B/t)\cdot C)\)]. For coefficients description see Table 4.](image-url)
from 0 to 0.5% significantly increased total VFA production (+100 mmol/L per percentage point of FSG inclusion; \(P=0.038\)) and slightly decreased lactic acid concentration in the caecum (−14 mmol/L per percentage point of FSG inclusion; \(P=0.091\)).

**DISCUSSION**

The results of this work show that FSG inclusion in diet up to 0.5% does not produce any significant effect on the apparent faecal digestibility of DM or its main components. However, we did observe that the values obtained for the digestibility of all fibrous fractions (TDF, SF, NDF and ADF) were always between 2 and 3% higher when the diets included FSG. Although galactomannan is not expected to affect the digestibility of the dietary components that are mainly digested in the small intestine, it could be expected that high fermentability of galactomannans in the caecum

1, G (mL/g DM), amount of gas produced per gram of DM at t time of incubation, \( A \) (mL/g DM), asymptotic gas production; \( B \) (h), time to achieve half of the asymptotic amount of gas; \( C \), constant determining the sharpness of the switching characteristic of the profile.

2, \( R_M \), maximum substrate degradation at time.

3, Time after the start of the incubation at which \( R_M \) occurs.

4, Change with respect to the blank (caecal inoculum without treatment).

5, Total volatile fatty acids.

6, Linear effect of FSG dietary inclusion: VFA \( (P=0.038) \) and lactic acid \( (P=0.091) \).

- \( a,b \): Means in a row not sharing the same letter are significantly different at \( P<0.05 \).

SEM: standard error of the means.

Fenugreek seed gum as a prebiotic for rabbits

**Effect of fenugreek seed gum (FSG) dietary inclusion in rabbit diets and pure FSG on the gas production profile**

Changes observed were a slight reduction in the caecal pH and a non-significant increase in some VFA, especially caproic acid. Some previous studies have observed that a reduction in caecal pH could inhibit the growth of some pathogenic bacteria, such as *E. coli* in rabbits (Gidenne and Licois, 2005), and an increase in the concentration of caproic acid in the caecum could also help to reduce the count of *E. coli* and *C. perfringens* (Skrivanova *et al.*, 2006; 2008). For that reason, it would be interesting to continue exploring the possible effect of FSG on the caecal environment with a greater inclusion in the diet, as inclusion up to 0.5% has not been able to produce relevant changes. *In vitro* gas production can reflect the extent to which substrates are fermented by gut microorganisms (Schroeder, 2000). Water-soluble fibres, like the galactomannan of FSG, seem to be highly fermentable in the rabbit caecum, leading to high gas production, the production of a greater amount of VFA and reduction of the \( \text{N-NH}_3 \) free at the final inoculum. Compared to the rabbit diets used in this work (Figure 1a), kinetic traits obtained for the pure FSG were characterised by higher substrate degradation rate, lower time to achieve the maximum rate of degradation and lower nitrogen content in the gas produced.

Most of the water-soluble polysaccharides and oligosaccharides are not digested in the small intestine but are rapidly fermented in the hindgut (Volek and Marounek, 2011). In our work, we observed that the dietary inclusion of FSG up to 0.5% did not lead to major significant changes in the caecal environment of growing rabbits at 94 d of age. The only changes observed were a slight reduction in the caecal pH and a non-significant increase in some VFA, especially caproic acid.

Some previous studies have observed that a reduction in caecal pH could inhibit the growth of some pathogenic bacteria, such as *E. coli* in rabbits (Gidenne and Licois, 2005), and an increase in the concentration of caproic acid in the caecum could also help to reduce the count of *E. coli* and *C. perfringens* (Skrivanova *et al.*, 2006; 2008). For that reason, it would be interesting to continue exploring the possible effect of FSG on the caecal environment with a greater inclusion in the diet, as inclusion up to 0.5% has not been able to produce relevant changes. *In vitro* gas production can reflect the extent to which substrates are fermented by gut microorganisms (Schroeder, 2000). Water-soluble fibres, like the galactomannan of FSG, seem to be highly fermentable in the rabbit caecum, leading to high gas production, the production of a greater amount of VFA and reduction of the \( \text{N-NH}_3 \) free at the final inoculum. Compared to the rabbit diets used in this work (Figure 1a), kinetic traits obtained for the pure FSG were characterised by higher substrate degradation rate, lower time to achieve the maximum rate of degradation and lower nitrogen content in the gas produced.

In summary, the results from this study suggest that fenugreek seed gum (FSG) can be a potential prebiotic for rabbits, as it affects the fermentation profile in the caecum, reducing the pH and increasing the amount of lactic acid. However, further studies are needed to evaluate the long-term effects on the digestive health and performance of rabbits.
clearly higher asymptotic gas production, which confirms the potential of FSG to be used by the fibrolytic microbiota of the rabbit’s caecum. Recently, Ocasio-Vega et al. (2018) compared gas production kinetics and in vitro traits of different fibrous substrates (cellulbiose, pectin, sugar beet pulp and wheat bran). When compared to a highly insoluble fibre (wheat straw), the other fibrous substrates lead to a higher gas production after in vitro incubation with a rabbit caecal inoculum, and the higher the SF content, the higher the gas production. Similar results were observed by Abad-Guamán et al. (2018) when comparing gas production of different substrates (pectin, sugar beet pulp and wheat straw) in a caecal inoculum for 28 h, where the volume of gas was proportional to the amount of substrate fermented. The higher microbial activity associated with the increased availability of a fermentable substrate is also usually associated with promoted microbial protein synthesis and reduced N-NH₃ level in the caecum (Carabaño et al., 2009; Trocino et al., 2013a). However, dietary inclusion of FSG up to 0.5% did not affect any of the kinetic parameters of the gas production model (Figure 1b). Bovera et al. (2010), comparing in vitro gas production of rabbit diets including mannan-oligosaccharides (MOS) up to 0.15% or supplemented with antibiotics, observed higher gas production and fermentation rate of MOS diets compared to the diet with antibiotics when gas production was fitted to the same model used in the present work (Groot et al., 1996). However, a linear increase in MOS inclusion from 0.05 to 0.15% did not affect gas production, although it seems to increase Rₚ and reduce. These results seem to indicate that the inclusion of low levels of fermentable substrates does not excessively affect in vitro gas production. The lack of differences in the kinetics traits observed with the inclusion of FSG may be due to a higher dilution of the inoculum in this work (2:1 and 4:1 in Bovera et al. (2010) and this work, respectively). In any case, dietary inclusion of FSG up to 0.5% caused a linear increase in the observed increase in the VFA content of the caecum during in vitro fermentation, due to its high fermentability, but without any relevant effect on the VFA profile. It can be concluded that pure FSG is highly and rapidly fermented in the rabbit caecum, decreasing the pH and N-NH₃ concentration and increasing total VFA level when it was in vitro incubated in a caecal inoculum. However, dietary inclusion of FSG up to 0.5%, although it linearly increased the total VFA level after in vitro incubation and decreased the caecal pH of young rabbits, did not affect the apparent digestibility and fermentation profile of the animals to any great extent. Based on these results, it would be convenient to carry out more studies on the fermentation pattern of this galactomannan, and on how its greater inclusion can affect growth performance, digestive health and microbiota in growing rabbits.

Acknowledgements: This study is supported by the Interministerial Commission for Science and Technology (CICYT) of the Spanish Government (AGL2017-85162-C2-1R), the Universitat Politècnica de València (Project 20180290; Spain), and the Higher School of Agriculture of Mateur of the Carthage University (Tunisia Republic).
