Allergy reduces the risk of meningioma: a meta-analysis

Peng-fei Wang1,*, Wen-Jun Ji2,*, Xiao-hui Zhang3, Shou-wei Li1 & Chang-Xiang Yan1

Meningiomas are the most common brain tumours; however, little is known regarding their aetiology. The data are inconsistent concerning atopic disease and the risk of developing meningioma. Thus, we conducted a meta-analysis to investigate the association between allergic conditions and the risk of developing meningioma. A systematic literature search was conducted using PubMed and Web of SCI from Jan 1979 to Feb 2016. Two investigators independently selected the relevant articles according to the inclusion criteria. Eight case-control studies and 2 cohort studies were included in the final analysis, comprising 5,679 meningioma cases and 55,621 control subjects. Compared with no history of allergy, the pooled odds ratio (OR) for allergic conditions was 0.81 (0.70–0.94) for meningioma in a random-effects meta-analysis. Inverse correlations of meningioma occurrence were also identified for asthma and eczema, in which the pooled ORs were 0.78 (0.70–0.86) and 0.78 (0.69–0.87), respectively. A reduced risk of meningioma occurrence was identified in hay fever; however, the association was weak (0.88, 95% CI = 0.78–0.99). The source of this heterogeneity could be the various confounding variables in individual studies. Overall, the current meta-analysis indicated that allergy reduced the risk of developing meningiomas. Large cohort studies are required to investigate this relationship.

Meningiomas are the most frequently reported brain tumours and account for 36.4% of all central nervous system (CNS) tumours. The incidence of meningioma increases with age and is 2.5 times higher in females than in males. Approximately 98.7% of meningiomas are reported as benign tumours and are classified as grade 1 according to the 2007 World Health Organization (WHO) grading system. Benign tumours are associated with improved patient survival; however, only 33% of meningioma patients exhibited no neurological deficits in a long-term follow-up. This unfavourable prognosis necessitates the need to develop potential preventive strategies. Unfortunately, a limited number of factors associated with the development of meningioma have been identified, including exposure to ionizing radiation, high body mass index (BMI) and a low level of physical activity.

Numerous studies have investigated the relationship between the occurrence of brain tumours and allergic conditions, including asthma, eczema, and hay fever. Atopic diseases have been inversely correlated with the risk of developing gliomas. However, there are no consistent findings that link meningiomas and atopic diseases, with the exception of eczema. In the two previous meta-analysis studies of atopy and the risk of meningioma development, no significant correlation between allergy history and meningioma was identified. However, recent studies have suggested a strong inverse association between allergy history (including allergy, asthma, eczema and hay fever) and meningiomas. Consequently, a meta-analysis was performed in the current study to address these conflicting results.

Results

Identification of relevant studies. Eleven articles, including 9 case-control studies and 3 cohort studies, that investigated the relationship between brain meningiomas and allergic conditions were identified through literature searches. There were three cohorts in Schwartzbaum’s study, but one was excluded due to expansive exposure definitions. One case-control study was removed because the data were included in a larger investigation. Finally, 5,679 patients with meningiomas and 55,621 control subjects were included in this meta-analysis. Two case-control studies conducted in southeast England shared a dataset that comprised 225 patient cases and 630 control subjects. However, the shared dataset was comparatively smaller than the total dataset (4% and 1% of the total, respectively), and we did not exclude the data as was done in previous studies.

Characteristics of the included studies. The details of the included subjects are presented in Table 1. All investigations were conducted in countries with a relatively high socioeconomic status, including Australia, New Zealand, Israel, North America and Europe, from 1977 to 2010. All meningioma cases were medically diagnosed. The odds ratio (OR) and 95% confidence interval (CI) provided by each study were adequately adjusted according to age and gender, and some values were controlled based on region and socioeconomic status (Table 2). An assessment of the studies included using the Newcastle Ottawa Scale (NOS) is presented in the supplementary files.

Meta-analysis of allergy and meningioma. Study-specific log ORs and the corresponding confounders adjusted are shown in Table 2. A patient history of allergic conditions was associated with a lower risk of meningiomas in a random model (Pooled OR = 0.81, 95% CI = 0.70–0.94, Fig. 1). A substantial degree of heterogeneity was identified in the included studies ($I^2 = 69.8\%$, $P = 0.000$). We identified an inverse association in the case-control study (Pooled OR = 0.79, 95% CI = 0.68–0.90); however, we failed to identify similar results in the cohort study (Pooled RR = 1.40, 95% CI = 0.49–3.98, Table 3). Moreover, the heterogeneity was not significantly reduced after stratification by study design, proxy rates or other characteristics. The exception to this finding was stratification by the adjusted cofounders (age and gender vs. age, gender, region, socioeconomic status and other factors), which demonstrated a reduction in heterogeneity in the later studies ($I^2 = 44.1\%$) compared with the alternative ($I^2 = 82.6\%$). Proxy respondents were less likely to report an allergic condition, which may lead to bias. A relatively high ratio of proxy respondents was apparent in two studies [10, 17], which were excluded in the further analyses. An inverse correlation of allergy occurrence with meningiomas persisted (Pooled OR = 0.79, 95% CI = 0.67–0.94). No publication bias was identified among the studies according to the Begg or Egger tests ($P = 0.152$ and $0.278$, respectively). As shown in the Funnel plots, most data points were within the funnel area for the risk of allergy with meningioma (Fig. 2).

Specific allergic conditions and meningiomas. The relationship between the risk of developing meningioma and the occurrence of specific allergic conditions was also investigated in 8 asthma studies, 9 eczema studies and 6 hay fever studies (Table 2). We identified an inverse relationship between asthma occurrence and the risk of developing meningiomas (Pooled OR = 0.78, 95% CI = 0.70–0.86), based on 16,491 participants, including 5,444 participants diagnosed with meningioma. A total of 5,424 cases and 25,658 controls were included in the study of eczema, which was inversely correlated with occurrence of meningioma (Pooled OR = 0.78, 95% CI = 0.69–0.87). There were 2,982

Table 1. Description of included studies regarding allergic status and risk of meningioma development.

| Schoemaker12 | 0.76 (0.61–0.96) | 0.85 (0.61–1.18) | 0.72 (0.51–1.02) | age (5-year group), gender, region, interview year, and SES (Townsend index) |
| Wigertz13 | 0.95 (0.82–1.10) | 0.94 (0.74–1.20) | 0.74 (0.60–0.91) | age, gender, education, country, and region |
| Berg-Beckhoff18 | 0.87 (0.66–1.14) | 0.78 (0.47–1.28) | 0.84 (0.61–1.15) | age, gender, socioeconomic status, region, and smoking |
| Claus16 | 0.6 (0.5–0.7) | 0.7 (0.6–0.9) | 0.8 (0.6–1.1) | age and gender |
| Wiemels15 | 0.64 (0.51–0.80) | 0.65 (0.50–0.86) | 0.95 (0.67–1.34) | age, gender, smoking, race and education |
| Turner8 | 0.77 (0.63–0.93) | 0.78 (0.59–1.03) | 0.74 (0.56–0.98) | age (5-year group), gender, region, country and education |
subjects with a diagnosis of meningioma and 23,096 control subjects included in the study, which indicates a lower margin of meningiomas (Pooled OR = 0.88, 95% CI = 0.78–0.99). No heterogeneity was identified in this analysis (Table 3).

Discussion
In the two previous meta-analyses, no relationship between allergy history and meningioma occurrence was identified. However, these findings were challenged by the inclusion of recently published data that demonstrated a significant inverse relationship between the two conditions. Our results indicated an inverse association between allergic conditions and meningiomas, with the inclusion of 5,679 meningioma cases and 55,621 controls. The association was also strong in the patients with asthma and eczema. We initially determined that hay fever was correlated with a reduced risk of meningiomas; however, this correlation was not obvious.

Our results were also supported by the fact that serum IgE levels (immunoglobulin E, a biomarker of atopic allergy) were reduced in patients with meningiomas compared with control subjects. IgE was likely to be an explanation for the mechanism behind allergy protected meningioma occurrence. Allergy mediated by IgE played a critical role in malignancies in the field of AllergoOncology. It was well observed that IgE acted superiorly to any immunoglobulins in targeting overexpressed tumor antigens, suggesting a positive role in natural immune surveillance. Furthermore, a hyper-reactive immune state system was more capable of recognizing and killing potentially cancerous cells. Moreover, macrophages, eosinophils and mast cells armed with IgE could become potent effectors in antitumor immunity. Reverse causality was possibly another explanation for the protective role of allergy. And this meant that the tumor itself suppressed immune function. Compared with benign meningiomas, aggressive meningiomas always exhibited immunological defects such as a decrease in CD4+ and CD8+ T lymphocytes, an increase in FOXP3+ Treg and PD-L1 (programmed death-ligand 1) levels.

Table 3. Pooled odd ratios (ORs) and 95% confidence intervals (CIs) of meningiomas in the subgroup analysis.

| Factor                        | No. of studies | No. of cases | No. of controls | Pooled ORs (95% CI) | I² | Phet heterogeneity |
|-------------------------------|----------------|--------------|-----------------|--------------------|----|-------------------|
| All studies                   | 10             | 5,679        | 55,621          | 0.81 (0.70–0.94)   | 69.80% | 0.000             |
| Case-control studies          | 8              | 5,610        | 11,573          | 0.79 (0.68–0.90)   | 68.60% | 0.002             |
| Cohort studies                | 2              | 69           | 44,048          | 1.40 (0.49–3.98)   | 73.80% | 0.051             |
| Adjusted cofounders (age and gender) | 3            | 1193         | 45,048          | 0.99 (0.46–2.14)   | 82.60% | 0.003             |
| Adjusted cofounders (e.g., age, gender, and region) | 7            | 4,486        | 10,573          | 0.82 (0.73–0.93)   | 44.10% | 0.097             |
| Lower proxy rate              | 2              | 5,155        | 53,721          | 0.79 (0.67–0.94)   | 74.50% | 0.000             |
| Higher proxy rate             | 8              | 524          | 1900            | 0.93 (0.74–1.17)   | 0.00% | 0.683             |
| Asthma                        | 8              | 5,444        | 11,047          | 0.78 (0.70–0.86)   | 0.00% | 0.593             |
| Eczema                        | 9              | 5,424        | 20,234          | 0.78 (0.69–0.87)   | 0.00% | 0.966             |
| Hay fever                     | 6              | 2,982        | 20,114          | 0.88 (0.78–0.99)   | 0.00% | 0.887             |
There were several limitations in our study. First, there was substantial heterogeneity in the analysis of meningiomas with allergy, i.e., 69.8% by I². The occurrence of meningiomas was likely to vary according to region, race, smoking history and socioeconomic status, which were considered in some of the included studies when calculating the log ORs. Following the stratification of adjusted confounders, the heterogeneity was reduced to 44.1% by I², which provided log ORs adjusted by at least 3 compounding variables (e.g., age, gender, and region). Moreover, the relationships between ionizing radiation exposure, BMI and physical activity and the risk of meningiomas were completely ignored in the included studies. This exclusion may provide one potential source of heterogeneity. Second, our analysis was mainly composed of case-control studies, which are sensitive to recall bias. However, the cohort studies included in the analysis consisted of small populations of cases and controls, which comprised 69 and 44,048 individuals, respectively. The results in the cohort studies were also completely different; however, the studies were conducted with very similar methods. Large cohort studies are necessary to confirm the inverse relationship. Third, all studies included in the final analysis were conducted in Europe, North America, Australia, New Zealand and Israel, countries with prosperous economies and advanced medicine. The conclusions outlined in the present study may not be applicable to other regions. In addition, publication bias was also a concern. Unpublished data demonstrating that allergic conditions are not correlated with meningiomas may exist. This missing information is likely to weaken the correlation of allergy with the risk of meningiomas.

In summary, allergic conditions were significantly associated with a reduced risk of developing meningiomas in this meta-analysis. We also identified a lower risk of meningiomas in subjects with asthma and eczema, whereas hay fever was weakly correlated with meningioma occurrence. Large cohort studies that include adequate samples remain necessary to investigate this relationship.

Methods

Literature search and study selection. Two authors independently conducted literature searches using PubMed and ISI Web of SCI from Jan 1979 to Feb 2016, using the search terms brain tumour, meningioma, allergy, atopy, asthma, eczema, and hay fever. The eligibility criteria for the studies included in this meta-analysis were as follows: (1) contained data from a case-control study or a cohort study, (2) a medical diagnosis of meningioma, (3) investigated the relationship between the risk of meningioma and allergy, and (4) provided an OR or relative risk (RR) with estimates of 95% CIs (or data to calculate CIs). In cases in which patients were included in more than one publication, the most recent study was selected for analysis.

Data extraction and assessment of study quality. All potential articles were independently reviewed and the data were extracted by two investigators; the variables included the first author's name, publication year, geographical origin, number of cases and controls, exposure definitions and risk estimates. Discrepancies were solved by discussion and consensus. We assessed the study quality using the NOS. Nine of the 10 included studies were awarded seven stars, whereas Brenner's studies were awarded six stars.

Statistical analysis. To compute the pooled ORs of allergy in meningiomas, we used the multivariate-adjusted risk estimates in each study rather than raw data. Study-specific log RRs or log ORs were weighted by the inverse of their variances. We present the pooled ORs in the random-effect models, which provide pooled results that are less precise but provide correct coverage. The heterogeneity among the studies was assessed by the method of DerSimonian and Laird Q. We quantified the heterogeneity using I². To investigate the potential origin of the heterogeneity, the included studies were further divided into subgroups according to the study characteristics (case-control vs. cohort study), proxy rates (high vs. low), and potential confounders adjusted in individual studies (age, gender vs. age, gender, region, social-economics states and other factors). Publication bias was assessed by Funnel plots, the Begg test, and the Egger test.
