(Dated: January 3, 2009)

Using an energy-independent non-Hermitian Hamiltonian approach to open systems, we fully describe transport through a sequence of potential barriers as external barriers are varied. Analyzing the complex eigenvalues of the non-Hermitian Hamiltonian model, a transition to a superradiant regime is shown to occur. Transport properties undergo a strong change at the superradiance transition, where the transmission is maximized and a drastic change in the structure of resonances is demonstrated. Finally, we analyze the effect of the superradiance transition in the Anderson localized regime.

I. INTRODUCTION

Open quantum systems are at the center of many research fields in physics today, ranging from quantum computing to transport in nanoscale and mesoscopic systems. In particular, electronic transport in the quantum regime can be considered one of the central subjects in modern solid state physics [1, 2]. Transport properties depend strongly on the degree of openness of the system. In important applications, the effect of the opening is large, and cannot be treated perturbatively. Thus, a consistent way to take the effect of the opening into account for arbitrary coupling strength between the system and the outside world is highly desirable. The effective non-Hermitian Hamiltonian approach to open quantum systems has been shown to be a very effective tool in addressing this issue [3, 4, 5, 6, 7].

In a typical situation, we have a discrete quantum system coupled to an external environment characterized by a continuum of states. Elimination of the continuum leads to an effective non-Hermitian Hamiltonian [8]. Analysis of the complex eigenvalues of the effective Hamiltonian reveals a general phenomenon, namely the segregation of decay widths (corresponding to the imaginary part of the complex eigenvalues). Specifically, in a system weakly coupled to the external world, all states tend to be similarly affected by the opening, but once the coupling reaches a critical value, a sharp reconstitution of the system occurs: almost the entire decay width is shared by a few short-lived states, leaving all other (long-lived) states effectively decoupled from the external world. The analogy between decay width segregation and Dicke superradiance [9] has been pointed out in Refs. [4, 5], although Dicke superradiance is associated with many-body systems, while width segregation occurs also in the one-body case. We will refer to this phenomenon as the “superradiance transition” in the following. Recently, great attention has been given to translating typical quantum optics effects, such as Dicke superradiance, into a solid state context [10]. In particular, the superradiance effect has been shown to occur in several mesoscopic systems [11].

The effective non-Hermitian Hamiltonian approach to open systems has been used mainly under the assumptions of Random Matrix Theory (RMT) [12, 13]. More realistic systems have also been studied, such as nuclei [14] and billiards [15]. In the latter example, segregation of resonance widths has already been demonstrated experimentally [16]. The effective non-Hermitian Hamiltonian technique has also been applied to phenomenological open tight-binding models in solid state physics [5, 17]. In these papers, the existence of a superradiance transition in such models was shown, but the explicit connections to realistic systems were not considered. For instance, one might ask whether in a realistic situation the coupling to the external environment can be increased up to the point where a superradiance transition occurs. Also, the energy dependence of the effective Hamiltonian is not easy to treat exactly, so one might ask in which realistic applications this energy dependence can be neglected.

In this paper, we consider the problem of transport through a sequence of potential barriers, see Fig. 1, which can be considered a paradigmatic model in solid state physics. This potential profile appears in real applications, such as semiconductor superlattices or one-dimensional arrays of quantum dots, and has been widely discussed in the literature [18, 19, 20].

The case of equally spaced potential barriers has been analyzed previously [18]. Here a different and more general approach to the problem is considered. First, we show that for weak tunneling coupling among the wells, an energy-independent effective Hamiltonian approach produces excellent agreement with an exact (numerical) treatment of the problem. Moreover, it is shown that even in this simple system a superradiance transition occurs as the coupling to the external world is increased by decreasing the widths of the external potential barriers. With the aid of the effective Hamiltonian approach, we recover several previous results and shed new light on the essential features of this well-studied model, allowing for a detailed understanding of the resonance structure. We emphasize that the powerful effective Hamiltonian formalism is not in any way limited to simple models of this type, and can be applied to situations where exact
treatment is difficult or impossible. In order to show this, we also analyze the case of random spacings among the potential barriers, and observe the consequences of the superradiance transition in the Anderson localization regime.

After briefly reviewing the effective Hamiltonian formalism in Sec. III, we build the effective Hamiltonian model for a sequence of potential barriers in Sec. III. In Sec. IV, the critical coupling value at which the superradiance transition occurs is derived, and in Sec. V we discuss the consequences of this transition on the resonance structure. In Sec. VI, we show that the maximum transmission is achieved at the superradiance transition, and we estimate analytically the exponential gain in transmission due to the superradiance effect. Finally, in Sec. VII we consider the superradiance transition in the Anderson localization regime, as a function of the disorder strength.

The effective Hamiltonian approach shows great promise in experimental applications, such as quantum dots [21] and photonic crystals [22]. We also believe that the superradiance transition can play a major role in explaining many of the results found in open mesoscopic systems [21], even if this effect has often been neglected in the literature.

II. EFFECTIVE HAMILTONIAN

We first sketch the essential features of the effective Hamiltonian approach to open quantum systems. Details of the derivation can be found in Refs. 3, 4, 7, 23.

Consider a discrete quantum system described by $N$ intrinsic basis states $|i⟩$ coupled to a continuum of states $|c⟩$, where $c = 1 \ldots M$ is a discrete quantum number labeling $M$ channels and $E$ is a continuum quantum number representing the energy. Let $A_i^j(E)$ be the transition amplitude between the intrinsic states and the continuum. Then the effective Hamiltonian for the intrinsic system, which fully takes into account its opening to the outside, can be written as:

$$H_{\text{eff}}(E) = H + \Delta(E) - \frac{i}{2} W(E)$$

with

$$W_{ij}(E) = 2\pi \sum_{c_{(\text{open})}} A_i^c(E) A_j^c(E)^* ,$$

where the sum is limited to the open channels, and

$$\Delta_{ij}(E) = \sum_c \text{P.v.} \int dE' \frac{A_i^c(E') A_j^c(E')^*}{E - E'} .$$

Assuming $W_{ij}(E)$ and $\Delta_{ij}(E)$ are smooth functions of the energy, their energy dependence can be neglected if the region of interest is concentrated in a small energy window. With the aid of the effective Hamiltonian, the transmission $T^{ab}(E)$ from channel $a$ to channel $b$ can be determined:

$$T^{ab}(E) = |Z^{ab}(E)|^2 ,$$

where

$$Z^{ab}(E) = \sum_{i,j=1}^N A_i^a \frac{1}{E - H_{\text{eff}}(A_j^b)^*}$$

is the transmission amplitude.

We can also write $T^{ab}(E)$ in a different way, diagonalizing the effective non-Hermitian Hamiltonian $H_{\text{eff}}$. Its eigenfunctions $|r⟩$ and $|i⟩$ form a bi-orthogonal complete set,

$$H_{\text{eff}} |r⟩ = \mathcal{E}_r |r⟩ , \quad ⟨i| H_{\text{eff}} = ⟨i| \mathcal{E}_r ,$$

and its eigenvalues are complex energies,

$$\mathcal{E}_r = E_r - \frac{i}{2} \Gamma_r ,$$

corresponding to resonances centered at $E_r$ with widths $\Gamma_r$. The decay amplitudes $A_i^a$ are transformed according to

$$A_i^a = \sum_j A_i^a ⟨i|r⟩ , \quad A_i^b = \sum_j ⟨i|j⟩ A_j^b ,$$

and the transition amplitudes are given by

$$Z^{ab}(E) = \sum_{r=1}^N A_r^a \frac{1}{E - \mathcal{E}_r} A_r^b .$$

The complex eigenvalues $\mathcal{E}$ of $H_{\text{eff}}$ coincide with the poles of $Z(E)$. It is clear that the properties of the complex eigenvalues of the effective Hamiltonian are very important for understanding the transport properties of the system.

As the coupling between the intrinsic states and the external continuum is increased, a rearrangement of the widths $\Gamma_r$ occurs. This rearrangement is usually referred to as the “superradiance” transition.

In order to understand the origin of this transition, we can consider a simplified version of Eq. (1): $H_{\text{eff}} = H_0 - \frac{i}{2} \gamma W$, where $\gamma$ is a parameter that controls the coupling strength with the external world (which now we assume to be of the same order of magnitude for all the intrinsic states), and $H_0$ is assumed to be diagonal with eigenvalues $E_0^a$. For small $\gamma$, the first-order complex eigenvalues of $H_{\text{eff}}$ are $\mathcal{E}_r = E_0^a - \frac{i}{2} \gamma W_{ii}$. If we consider the opposite limit of large $\gamma$, $H_0$ can be viewed as a perturbation acting on $W$. Due to the factorized structure evident in Eq. (2), $W$ has only $M$ non-zero eigenvalues for $M < N$. Thus, only $M$ states will have a decay width in the limit of large coupling, while all others will have zero width to first order. Therefore, as the coupling increases, all widths initially increase proportionally to $\gamma$, but at large couplings only $M$ of the
widths continue to increase, while the remaining \( N - M \)
widths approach zero. This simple example suggests that
a transition between these two regimes may take place at
a critical value of \( \gamma \). Roughly, the transition occurs when
\( \gamma/D \approx 1 [21, 22] \), where \( D \) is the mean level spac-
ing of \( H_0 \). Note that the qualitative criterion \( \gamma/D \approx 1 \)
for the transition to superradiance is valid in the case of
uniform density of states and negligible energy shift;
when the density of states is not uniform, the transition
to superradiance occurs as a hierarchical process [24]. In
the case of a non-negligible energy shift, see the analysis
in Sec. IV.

From the above discussion it should be clear that the
superradiance transition emerges in the non-Hermitian
effective Hamiltonian approach as a general phenomenon,
depending not on the details of the system, but only on
the factorized structure of \( W \).

III. EFFECTIVE HAMILTONIAN FOR A
SEQUENCE OF POTENTIAL BARRIERS

Let us consider quantum transport through a sequence
of \( N + 1 \) potential barriers, see Fig. 1 of width \( \Delta \), height
\( V_0 \), and inter-barrier separation \( L \). The transport prop-
erties will be analyzed as we change the external barrier
width \( \Delta_{ext} \) while keeping all the other barriers fixed.

\[
\Omega = 2\alpha|\psi(x_0)|^2 = \frac{2\alpha^2 E_0}{V_0(1 + \alpha L/2)} \exp(-\alpha\Delta), \tag{10}
\]

where \( \alpha = \sqrt{V_0 - E_0} \), \( k = \sqrt{E_0} \), \( \psi \) is a basis wave
function localized in a single potential well, and \( x_0 \) is a
point in the middle of a potential barrier immediately adjacent
to that well. Due to the tunneling coupling among the
wells, the eigenenergies of the closed system form a
miniband around \( E_0 \), see Eq. (10) in the next Section.

The outside world is characterized by the scattering
states to the left, \( |L, E\rangle \), and to the right, \( |R, E\rangle \), of
the sequence of potential barriers. Due to the coupling to the
scattering states, the states \( |i\rangle \) and \( |N\rangle \) acquire a finite
width \( \gamma \) and an energy shift \( \delta \), which can be computed
following Refs. [27, 28]. In the case of a varying external
barrier width \( \Delta_{ext} \), one obtains:

\[
\gamma = \frac{8\alpha^2 E_0}{V_0(1 + \alpha L/2)} \exp(-2\alpha\Delta_{ext}), \tag{11}
\]

\[
\delta = \frac{\gamma^2 - \alpha^2}{4ak^2}. \tag{12}
\]

Note that the shift \( \delta \) vanishes for \( E_0 = V_0/2 \); otherwise
the sign of \( \delta \) is given by the sign of \( E_0 - V_0/2 \).

Analogous expressions when the external potential height
\( V_{ext} \) is varied can be computed by extending the
methods of [27], but are more complicated and will not
be reported here.

We can now write the full effective Hamiltonian for the
miniband centered at energy \( E_0 \) as:

\[
H_{eff} = \begin{pmatrix}
E_0 + \delta - \frac{\gamma^2}{2} & \Omega & 0 & \ldots & 0 \\
\Omega & E_0 & \Omega & \ldots & 0 \\
0 & \Omega & E_0 & \ldots & 0 \\
\ldots & \ldots & \ldots & \ldots & \ldots \\
0 & 0 & 0 & E_0 + \delta - \frac{\gamma^2}{2} & \ldots 
\end{pmatrix}
\]

Using Eqs. (11) and (12), the transmission through the se-
sequence of potential barriers becomes

\[ T(E) = \left| \frac{(\gamma/\Omega)}{\prod_{k=1}^{N} (E - \varepsilon_k)/\Omega} \right|^2 . \]  

(13)

From Eq. 13 we see that the spectrum of complex eigenvalues \( \varepsilon_k = E_k - \frac{\gamma}{2} \Gamma_k \) of \( H_{\text{eff}} \) determines the transmission through the system.

In order to show the range of validity of the effective Hamiltonian model, we compute the normalized integrated transmission:

\[ S = \frac{1}{4\Omega} \int_{E_{\text{min}}}^{E_{\text{max}}} T(E)dE , \]  

(14)

where the interval \([E_{\text{min}}, E_{\text{max}}]\) includes the entire miniband centered at \( E_0 \).

The predictions of Eq. 13 are now compared with the exact numerical results. The effective Hamiltonian approach is expected to break down for small values of \( \alpha\Delta \). In Fig. 2 we plot \( S \) vs \( \alpha\Delta \) for a system of \( N = 10 \) wells, with \( E_0 \approx 20 \) fixed, so that \( \alpha \) remains constant. From the figure we can see that the effective Hamiltonian approximation gives excellent results for \( \alpha\Delta \gg 1 \). Note also that \( S \) is independent of \( \Delta \) for \( \Delta/\Delta_{\text{ext}} = 2 \) in the weak coupling limit, \( \alpha\Delta \gg 1 \), as indicated by a dashed line in Fig. 2. This follows from the fact that \( \gamma/\Omega \) is independent of \( \Delta \) when \( \Delta/\Delta_{\text{ext}} = 2 \), see Eq. 10 and Eq. 11. Note that we also compared the results obtained with the effective Hamiltonian approach with available analytical results found in the literature [18], and found excellent agreement in the regime \( \alpha\Delta \gg 1 \).

IV. SUPERRADIANCE TRANSITION

We will now analyze the superradiance transition that occurs in the effective Hamiltonian model built in the previous section.

Diagonalization of the intrinsic Hamiltonian leads to the energy levels [1]:

\[ w_q = E_0 - 2\Omega \cos(q\pi/(N+1)) , \]  

(15)

with \( q = 1 \ldots N \). Due to coupling with the external world, the energy levels \( w_q \) will acquire decay widths \( \Gamma_q \). These decay widths are the imaginary parts of the eigenvalues of the effective Hamiltonian, Eq. 12, and, for \( \gamma \ll 1 \), they can be written as:

\[ \Gamma_q = \frac{4\gamma}{N+1} \sin^2(q\pi/(N+1)) . \]  

(16)

We see that all widths increase proportionally to \( \gamma \) for small coupling. In the opposite limit of large \( \gamma \), only \( M \) states (where \( M \) is the number of channels) will have a width proportional to \( \gamma \), while the widths of the remaining states fall off as \( 1/\gamma \), as explained above in Sec. 11. In our case we have \( M = 2 \), corresponding to one scattering channel each on the left and right. The two superradiant states correspond to the two non-zero eigenvalues of the matrix \( W \) (Eq. 11).

In order to find the critical value of the parameter \( \gamma \) at which the superradiance transition occurs, we may analyze the average width \( \langle \Gamma \rangle \) of the \( N - M \) narrowest widths as a function of the coupling \( \gamma \). Fig. 3 At the critical value of \( \gamma \), the average width \( \langle \Gamma \rangle \) peaks and begins to decrease. This is the signature of the superradiance transition.

We can evaluate this critical value of \( \gamma \) using the criterion discussed earlier in Sec. 11 \( \langle \Gamma \rangle/D \approx 1 \). Consider first the simpler case of vanishing energy shift \( \delta \). The average width \( \langle \Gamma \rangle \) is then given by the perturbative expression, Eq. 10, taking into account that \( \langle \sin^2(q\pi/(N+1)) \rangle \rightarrow 1/2 \) for large \( N \). Moreover, from Eq. 15 we find that for large \( N \) the mean level spacing becomes \( D = 4\Omega/N \), so we obtain:

\[ \frac{\langle \Gamma \rangle}{D} = \frac{1}{2} \frac{\gamma}{\Omega} . \]  

(17)

Thus, for \( \delta = 0 \), the criticality criterion \( \langle \Gamma \rangle/D \approx 1 \) implies \( \gamma \approx 2\Omega \). Note that this happens when \( \Delta_{\text{ext}} = \Delta/2 \) (see Eqs. 10 and 11), so that the superradiance transition occurs when the external barriers are precisely half as wide as the internal ones.

Typical examples for large and small \( N \) are presented in Fig. 3, where \( E_0 = V_0/2 \) to ensure that the energy shift \( \delta = 0 \). The \( N = 100 \) example in the upper panel illustrates that the estimate \( \gamma \approx 2\Omega \) for the critical value works very well at large \( N \).
In this section, we focus on the case of $N = 5$ potential wells. As discussed above in Sec. V, a signature of the superradiance transition is the segregation of resonance widths above the critical coupling. The system under study has two open channels, thus we expect two resonance widths (associated with superradiant states) to continue increasing above the transition, while the remaining widths approach zero. In Fig. 4 we show the trajectories of the complex eigenvalues $E_i$ of the effective Hamiltonian as $\Delta/\Delta_{ext}$ is increased. Note that the real parts of the eigenvalues experience a leftward shift with increasing coupling, since in this case $E_0 < V_0/2$, so that $\delta < 0$.

![FIG. 3: The average width, normalized to the mean level spacing, is shown as a function of $\gamma/\Omega$ for the case $\Delta = 0.15$ and $E_0 \approx V_0/2$. When $N$ is large, the transition to superradiance is shown to occur at $\gamma/\Omega \approx 2$, in agreement with the analytical estimation, see text. The solid line corresponds to an average over all $N$ widths, while the symbols are obtained by averaging over the $N - 2$ smallest widths. The quantities plotted are dimensionless.](image)

We now turn to the $\delta \neq 0$ case. Both the density of states and the resonance widths are modified, as we can see using second order perturbation theory in small $\gamma$:

$$E_q = w_q + (\delta - i\gamma/2)\frac{4\sin^2 \phi_q}{N + 1} + (\delta^2 - \gamma^2/4 - i\gamma\delta) \sum_{p \neq q} \frac{A_{qp}^2}{w_q - w_p},$$

where $A_{qp} = (2/N)^2(1 + (-1)^{q+p})^2 \sin^2 \phi_q \sin^2 \phi_p$ and $\phi_q = \pi q/(N + 1)$.

Clearly, the local level spacings $\Delta_q(\gamma) = \text{Re}(E_q - E_{q-1})$ and the local resonance widths $\Gamma_q(\gamma) = -\text{Im}(E_q + E_{q-1})$ depend on the index $q$ as well as the coupling $\gamma$. A reasonable hypothesis is that the superradiance transition occurs when the resonances begin to overlap locally, i.e., $\Gamma_q(\gamma) \approx D_q(\gamma)$ for some $q$. We have confirmed numerically that this local overlap criterion gives an excellent approximation for the critical value of $\gamma$ at which the superradiance transition occurs, for any $\delta$. Unfortunately, second order perturbation theory does not provide an accurate analytical estimate for $\gamma$, confirming that the physics is highly non-perturbative near the superradiance transition.

V. RESONANCE STRUCTURE

To show the consequences of the superradiance transition on the transport properties, here we analyze the resonance structure, by considering the transmission $T(E)$. Note that the resonance structure can be directly resolved experimentally, see [20].

![FIG. 4: The evolution in the complex plane of the eigenvalues of the effective Hamiltonian is shown as the ratio $\Delta/\Delta_{ext}$ is varied. A system of 5 intrinsic states in the $E_0 \approx 2$ miniband is considered, with $\Delta = 0.2$. The emergence of two superradiant states is clearly visible above the transition. Here and in the following figures, we use units $\hbar^2/2m_e = 1$, so that if lengths $\Delta$, $\Delta_{ext}$, and $L$ are measured in nm, energies are calculated in units of 0.038 eV.](image)

In Fig. 5 the transmission is shown as a function of the energy for several values of $\Delta/\Delta_{ext}$. For small coupling, $\Delta/\Delta_{ext} = 1.5$, we have $N = 5$ narrow resonances as expected. As we decrease the external barrier widths, the transmission increases and near $\Delta/\Delta_{ext} = 2$ two of the resonances start to overlap. At $\Delta/\Delta_{ext} = 2.15$, they merge, forming a broad resonance. This shows that the superradiance transition has a clear signature in the resonance structure. As the external barrier widths continue to decrease, the height of the superradiant resonance decreases (see the case $\Delta/\Delta_{ext} = 2.4$ in Fig. 5), until it disappears entirely for large $\Delta/\Delta_{ext}$, due to destructive interference between the two superradiant states. In this limit, $N - 2$ narrow resonances remains. The fact that two resonances disappear for very large coupling is not surprising; indeed in the absence of the two external barriers, we simply have a system of $N - 2$ wells. What is interesting is that the two individual resonances disap-
pear long before the external barriers vanish, indeed immediately after the superradiance transition. Note also in Fig. 5 that results obtained from the effective Hamiltonian model are indistinguishable from numerical results obtained by matching the wave functions.

The behavior we have demonstrated for the case of $N = 5$ potential wells generalizes easily to a larger number of wells, with important quantitative differences. Indeed, for a longer chain, the superradiant states disappear much faster as we increase $\Delta/\Delta_{\text{ext}}$ above the critical value, i.e., the superradiance transition becomes increasingly sharp. Interestingly, the critical value of $\Delta/\Delta_{\text{ext}}$ becomes both $N$-independent and $E_0$-independent in the large-$N$ limit, with the transition occurring at $\Delta/\Delta_{\text{ext}} = 2$, in agreement with previous results [18, 20].

VI. INTEGRATED TRANSMISSION

Another interesting quantity to analyze is the integrated transmission $S$, Eq. (14), as a function of $\Delta/\Delta_{\text{ext}}$. The quantitative enhancement in $S$ when external barrier parameters are adjusted is important in applications, for instance in the design of electron band-pass filters for semiconductor superlattices [18]. From Fig. 6 we see that $S$ reaches a maximum as a function of the external barrier width. Fig. 6 also shows that the value of $S$ for $\Delta_{\text{ext}} \ll \Delta$ is the same as for $\Delta_{\text{ext}} = \Delta$. This is due to the fact that $S$ becomes $N$-independent for large $N$, as shown in Fig. 6 as the external barriers disappear we are eventually left with a sequence of $N - 2$ potential wells, which has the same value of the integrated transmission $S$ as the original sequence of $N$ wells.

FIG. 5: The transmission is shown as a function of energy for a system of $N = 5$ potential wells, for the same parameters as in Fig. 4 and several values of $\Delta/\Delta_{\text{ext}}$. The exact transmission, black solid line, is compared with the result obtained from the effective Hamiltonian model, Eq. (13), indicated by red circles. The two superradiant states merge at $\Delta/\Delta_{\text{ext}} = 2.15$, and then disappear entirely, leaving behind $N - 2$ resonances, see $\Delta/\Delta_{\text{ext}} = 2.4$.

FIG. 6: The integrated transmission $S$ is shown as a function of $\Delta/\Delta_{\text{ext}}$, for different numbers of wells. The symbols refer to an exact numerical calculation, while the effective Hamiltonian result is indicated by the black and red dashed curves. The horizontal dashed line represents the value of $S$ for $\Delta = \Delta_{\text{ext}}$. In this example, we use $E_0 \approx 20$ and $\Delta = 0.15$.

FIG. 7: The critical value of $\gamma/\Omega$ at which the superradiance transition occurs (solid curve) is compared with the critical value at which the integrated transmission has a maximum (circles). For $N = 100$ (upper panel), the two coincide, while they differ for $N = 5$ (lower panel), see the discussion in the text. Here $\Delta = 0.2$.

The maximum of the integrated transmission can be related to the superradiance transition. In Fig. 7 we show the critical value of $\gamma/\Omega$ at which the average width $\langle \Gamma \rangle$ has a maximum (signaling the superradiance transition, see Fig. 3), compared with the value of $\gamma/\Omega$ at
using a different approach. Note also that the gain is exponential in the internal barrier width $\Delta$.

VII. ANDERSON LOCALIZATION REGIME

In the previous sections we considered an effective Hamiltonian \[ \tilde{H} \] with equal diagonal energies $E_0$. Here we want to apply the effective Hamiltonian technique to the case of random variations of the diagonal energies: $E_0 \pm \delta E_0$, where $\delta E_0$ is a random variable uniformly distributed in $[-W/2, +W/2]$, and $W$ is a disorder parameter. A first analysis of this model can be found in Ref. [29].

Random variation in the diagonal energies can be thought of as a consequence of small random fluctuations $\delta L$ of the well widths $L$. For $E_0 \ll V_0$, the eigenenergies of a finite potential well may be approximated by the eigenenergies of an infinite potential well, $E_0 = n^2\pi^2/L^2$, where $n = 1, 2, \ldots$. For small fluctuations $\delta L/L \ll 1$, we have

$$\delta E_0 = \frac{2n^2\pi^2}{L^2} \delta L = -C \delta L,$$

where $C = 2n^2\pi^2/L^3$. Thus, a random variation of $\delta E_0$ in $[-W/2, +W/2]$ corresponds to a random variation of $\delta L$ in $[-W/2C, +W/2C]$.

The effective non-Hermitian Hamiltonian with diagonal disorder is equivalent to an open Anderson tight binding model [2, 30]. The eigenstates of the Anderson model are exponentially localized on the system sites, with exponential tails given by $\exp(-x/L_{\text{loc}})$, where for weak disorder, the localization length $L_{\text{loc}}$ at the center of the energy band can be written as [31]:

$$L_{\text{loc}} \approx 105.2 \left( \frac{W}{\Omega} \right)^{-2}.$$  \hspace{1cm} (22)

For $L_{\text{loc}} \ll N$, the transmission decays exponentially with $N$; this is the localized regime. Note that for zero disorder, the transmission is $N$-independent, as we showed in the previous section. The condition $L_{\text{loc}} = N$ defines a critical value of $(W/\Omega)_{cr}$ for the localized regime, at any given $N$. In the localized regime, the transmission is log-normally distributed, and we have [3]:

$$(- \ln T) = 2 \frac{N}{L_{\text{loc}}^{cr}} + \text{Const}.$$ \hspace{1cm} (23)

In Fig. 8 we show the average transmission as a function of the disorder strength for two different degrees of opening of the system. The results obtained using an effective Hamiltonian with diagonal disorder are compared with numerical simulations for the disordered sequence of potential wells. The agreement is excellent up to a large value of the disorder, where of course our approximations...
have analyzed the effective Hamiltonian, neglecting the external world? To answer these questions, we open up the system? Will the localization length change as we vary the coupling of the system with the external world? Will a maximum of the transmission still exist as we vary the degree of openness of the system. The effect of the opening on Anderson localization was studied in a closed disordered chain or for fixed opening, while in our case we can vary the degree of openness of the system. The effect of the opening on Anderson localization is not obvious. Will a maximum of the transmission still exist as we vary the coupling of the system with the external world? Will the localization length change as we open up the system? To answer these questions, we have analyzed the effective Hamiltonian, neglecting the role of the energy shift, i.e., we set $\delta = 0$ in the following. In Fig. 10 we compute the average of $-\langle \ln T \rangle$ over $10^5$ realizations as a function of $\gamma/\Omega$. The energy is fixed at $E = E_0$. As we vary $\gamma/\Omega$, the average transmission reaches a maximum, just as in the disorder-free case.

Interestingly, as the disorder strength increases, the transmission maximum (associated with the superradiance transition) shifts to ever higher values of the coupling strength $\gamma$. Indeed, the mean level spacing $D$ increases with growing disorder, so that the condition $\langle \Gamma \rangle / D \approx 1$ for the superradiance transition to occur will be satisfied at increasingly larger values of $\gamma/\Omega$. For weak disorder, the disorder-induced correction to $D$ is second order in the disorder strength, so $(\gamma/\Omega)_{cr} = 2 + O(W^2/\Omega^2)$. In the opposite regime of large $W/\Omega$ we find $D \approx 2\Omega (1 + W/2\Omega)/N$, and the critical coupling is predicted to be $(\gamma/\Omega)_{cr} \approx 1 + W/2\Omega$. This estimate works quite well, as shown by the vertical lines in Fig. 10. Note that the curves shown in Fig. 10 have been found to be independent of $N$.

Finally in Fig. 11 we show $\langle \ln T \rangle$ versus $N$ for $W/\Omega = 2$, and for two different values of the external barrier width: $\Delta/\Delta_{ext} = 1$ and $\Delta/\Delta_{ext} = 2$, where the maximum of the transmission occurs. Fig. 11 shows that Eq. 23 works very well in both situations, even though the transmission is enhanced when $\Delta/\Delta_{ext} = 2$, for all values of $N$. Thus, the localization length in a disordered 1D model is not affected by the opening, but the transmission is.

VIII. CONCLUSION

We have analyzed quantum transport through a finite sequence of potential barriers, a paradigmatic model for transport in solid state physics. In this paper, the effective non-Hermitian Hamiltonian approach has been used to analyze the transmission through this class of systems. The main results of our work are the following: i) we show that for weak or moderate tunneling coupling among the potential wells, the system is well described by an energy-independent effective Hamiltonian. Knowledge of the complex eigenvalues of the effective Hamiltonian is sufficient to study transport through the system. ii) As the coupling to the continuum is increased
by adjusting the width of the external barriers, a superradiance transition (or Dicke effect) occurs. Analysis of the complex eigenvalues of the effective Hamiltonian allows us to determine the critical coupling associated with this transition. iii) The superradiance transition has strong effects on the transport properties: specifically, the transmission through the system is maximized at the superradiance transition. An expression for the transmission gain due to the superradiance transition is derived. Moreover the resonance structure is drastically affected: at the superradiance transition, we have the formation of a broad resonance corresponding to the superradiant states. Beyond the transition, this broad resonance disappears, and the number of resonances decreases by two. iv) The case of a disordered sequence of potential barriers has been also analyzed. In the presence of disorder, Anderson localization occurs. We have shown the localization length remains constant as the opening changes, but the transmission has a maximum as a function of the coupling to the external world. The critical value of the coupling increases with the degree of disorder, and we obtain an estimate of the critical value for strong and weak disorder, based on the superradiance mechanism.

In the future it will be interesting to study the consequences of the superradiance transition beyond the single particle approximation, where electron-electron interactions play an important role.
