The interplay between two basic quantities – quantum communication and information – is investigated. Quantum communication is an important resource for quantum states shared by two parties and is directly related to entanglement. Recently, the amount of local information that can be drawn from a state has been shown to be closely related to the non-local properties of the state. Here we consider both formation and extraction processes, and analyze informational resources as a function of quantum communication. The resulting diagrams in information space allow us to observe phase-like transitions when correlations become classical.

Quantum communication (QC) – the sending of qubits between two parties – is a primitive concept in quantum information theory. Entanglement cannot be created without it, and conversely, entanglement between two parties can be used to communicate quantum information through teleportation\textsuperscript{(1)}. The amount of quantum communication needed to prepare a state, and the amount of quantum communication that a state enables one to perform, are fundamental properties of states shared by two parties. This amount, is identical to the entanglement cost $E_c$\textsuperscript{(2)} and entanglement of distillation $E_D$\textsuperscript{(3)} respectively. Perhaps surprisingly, these two quantities are different\textsuperscript{(4)}. There are even states which are "bound" in the sense that quantum communication is needed to create it, but nothing can be obtained from it\textsuperscript{(5)}. Yet QC is a distinct notion from entanglement. For example, one may need to use a large amount of QC while creating some state of low $E_c$, in order to save some other resource. In the present paper we will consider such a situation. The second primitive resource of interest will be information which quantifies how pure a state is. The motivation comes from (both classical or quantum) thermodynamics: it is known that bits that are in a pure state can be used to extract physical work from a single heat bath\textsuperscript{(6)}, and conversely work is required to reset mixed states to a pure form\textsuperscript{(7,8)}.

For distant parties, in order to use information to perform such tasks, it must first be localized. In\textsuperscript{(9)} we considered how much information (i.e., pure states) can be localized (or drawn) from a state shared between two parties. Thus far, the amount of information needed to prepare a state has not been considered, a possible exception being in\textsuperscript{(10)} where it was noted that there was a thermodynamical irreversibility between preparation and measurement for ensembles of certain pure product states. However, given the central role of quantum communication and information, it would be of considerable importance to understand the interplay between these two primitive resources. In this Letter, we attempt to lay the foundation for this study by examining how much information is needed to prepare a state and how much can be extracted from it as a function of quantum communication. For a given state, this produces a curve in information space. The shapes of the curve fall into a number of distinctive categories which classify the state and only a small number of parameters are needed to characterize them. The curves for pure states can be calculated exactly, and they are represented by a one parameter family of lines of constant slope. The diagrams exhibit features reminiscent of thermodynamics, and phase-like transitions (cf.\textsuperscript{(11)}) are observed.

An important quantity that emerges in this study is the information surplus $\Delta_f$. It quantifies the additional information that is needed to prepare a state when quantum communication resources are minimized. $\Delta_f$ tells us how much information is dissipated during the formation of a state and is therefore closely related to the irreversibility of state preparation and therefore, to the difference between the entanglement of distillation and entanglement cost. When it is zero, there is no irreversibility in entanglement manipulations. Examples of states with $\Delta_f = 0$ include pure states, and states with an optimal decomposition\textsuperscript{(3)} which is locally orthogonal.

Consider two parties in distant labs, who can perform local unitary operations, dephasing\textsuperscript{(12)}, and classical communication. It turns out to be simpler to substitute measurements with dephasing operations, since we no longer need to keep track of the informational cost of resetting the measuring device. (This cost was noted by Landauer\textsuperscript{(3)} and used by Bennett\textsuperscript{(8)} to exorcize Maxwell’s demon.) The classical communication channel can also be thought of as a dephasing channel. Finally, we allow Alice and Bob to add noise (states which are proportional to the identity matrix) since pure noise contains no information. Note that we are only interesting in accounting for resources that are "used up" during the preparation procedure. For example, a pure state which is used and then reset to its original state at the end of the procedure, does not cost anything.

Consider now the information extraction process of\textsuperscript{(3)}. If the two parties have access to a quantum channel, and share a state $\varrho_{AB}$, they can extract all the information from the state

\[ I = n - S(\varrho_{AB}) \]  

(1)
where \( n \) is the number of qubits of the state, and \( S(\rho_{AB}) \) is its Von Neumann entropy. Put another way, the state can be compressed, leaving \( I \) pure qubits. However, if two parties do not have access to a quantum channel, and can only perform local operations and communicate classically (LOCC), then in general, they will be able to draw less local information from the state. In [9] we defined the notion of the deficit \( \Delta \) to quantify the information that can no longer be drawn under LOCC. For pure states, it was proven that \( \Delta \) was equal to the amount of distillable entanglement in the state.

Let us now turn to formation processes and define \( \Delta_f(Q) \) as follows. Given an amount of quantum communication \( Q \), the amount of information (pure states) needed to prepare the state \( \rho_{AB} \) under LOCC is given by \( I_f(Q) \). Clearly at least \( E_c \) bits of quantum communication are necessary. In general, \( I_f(Q) \) will be greater than the information content \( I \). The surplus is then

\[
\Delta_f(Q) = I_f(Q) - I.
\]

The two end points are of particular interest i.e. \( \Delta_f \equiv \Delta_f(E_c) \) where quantum communication is minimized, and \( \Delta_f(E_r) = 0 \) where we use the quantum channel enough times that \( I_f(E_r) = I \). Clearly \( E_c \leq E_r \leq \min\{S(\rho_A), S(\rho_B)\} \) where \( \rho_A \) is obtained by tracing out on Bob’s system. This rough bound is obtained by noting that at a minimum, Alice or Bob can prepare the entire system locally, and then send it to the other party through the quantum channel (after compressing it). We will obtain a tight bound later in this paper.

The general procedure for state preparation is that Alice uses a classical instruction set (ancilla in a classical state) with probability distribution matching that of the decomposition which is optimal for a given \( Q \). Since the instruction set contains classical information, it can be passed back and forth between Alice and Bob. Additionally they need \( n \) pure standard states. The pure states are then correlated with the ancilla, and then sent. The ancilla need not be altered by this procedure, and can be reset and then reused and so at worst we have \( I_f \equiv I_f(E_c) \leq n \) and \( \Delta_f \leq S(\rho_{AB}) \). We will shortly describe how one can do better by extracting information from correlations between the ancilla and the state.

The pairs \((Q, I_f(Q))\) form curves in information space. In Figure 1 we show a typical curve which we now explain. Since we will be comparing the formation curves to extraction curves, we will adopt the convention that \( I_f(Q) \) and \( Q \) will be plotted on the negative axis since we are using up resources. It can be shown that \( I_f(Q) \) is concave, monotonic and continuous. To prove concavity, we take the limit of many copies of the state \( \rho_{AB} \). Then given any two protocols, we can always toss a coin weighted with probabilities \( p \) and \( 1 - p \) and perform one of the protocols with this probability. There will always be a protocol which is at least as good as this. Monotonicity is obvious (additional quantum communication can only help), and continuity follows from monotonicity, and the existence of the probabilistic protocol.

The probabilistic protocol can be drawn as a straight line between the points \((E_r, I_f(E_r))\) and \((E_c, I_f(E_c))\). There may however exist a protocol which has a lower \( I_f(Q) \) than this straight line, i.e. the curve \( I_f(Q) \) satisfies

\[
I_f(Q) \leq I + \frac{I(E_r) - I_f(E_c)}{E_c - E_r}(Q - E_r) \quad (3)
\]

Let us now look at extraction processes. The idea is that we draw both local information (pure separable states), and distill singlets. The singlets allow one to perform teleportations, so that we are in fact, extracting the potential to use a quantum channel. We can also consider the case where we use the quantum channel to assist in the information extraction process. We can therefore write the extractable information \( I_t(Q) \) as a function of \( Q \). When \( Q \) is positive, we distill singlets at the same time as drawing information, and when \( Q \) is negative, we are using the quantum channel \( Q \) times to assist in the extraction (see also Figure 1).

There appear to be at least three special points on the curve. The first, is the point \( I_t \equiv I_t(0) \). This was considered in [10] when we draw maximal local information without the aid of a quantum channel. Another special point is the usual entanglement distillation procedure \( I_g = I_t(E_D) \). The quantity \( I_g \) is the amount of local information extractable from the ”garbage” left over from distillation. \( I_g \) can be negative as information may need to be added to the system in order to distill all the available entanglement. Finally, \( I = I_t(E_I) \) is the point where
we use the quantum channel enough times that we can extract all the available information. This is the same number of times that the quantum channel is needed to prepare the state without any information surplus since both procedures are now reversible.

Just as with the formation curve, \( I_t(Q) \) is convex, continuous and monotonic. For \( Q \geq 0 \) there is an upper bound on the extraction curve due to the classical/quantum complementarity of \[ I + Q \leq I_f \] (4)

It arises because one bit of local information can be drawn from each distilled singlet, destroying the entanglement. One might suppose that the complementarity relation (4) can be extended into the region \( Q < 0 \). Perhaps surprisingly, this is not the case, and we have found that a small amount of quantum communication can free up a large amount of information. In Figure 2, we plot the region occupied by pure states. For extraction processes, pure states saturate the bound of Eq. (4). For formation processes they are represented as points.

In general, if \( \Delta_f = 0 \) then \( E_c = E_D \). Examples include mixtures of locally orthogonal pure states. The converse is not true, at least for single copies, as there are separable states such as those of \[ \frac{1}{2} \] which have \( \Delta_f \neq 0 \), and \( \Delta \neq 0 \).

It therefore appears that \( \Delta_f \) is not a function of the entropy of the state, or of the entanglement, but rather, shows how chaotic the quantum correlations are. It can also be thought of as the information that is dissipated during a process, while \( \Delta \) can be thought of as the bound information which cannot be extracted under LOCC.

Figure 2d shows the curves for some different types of states. It is interesting the extent to which one can classify the different states just by examining the diagrams in information space.

The quantities we are discussing have (direct or metaphorical) connections with thermodynamics. Local information can be used to draw physical work, and quantum communication has been likened to quantum logical work \[ [14] \]. One is therefore tempted to investigate whether there can be some effects similar to phase transitions. Indeed, we will demonstrate such an effect for a family of mixed states where the transition is of second order, in that the derivative of our curves will behave in a discontinuous way.

To this end we need to know more about \( E_r \) and \( I_r \). Consider the notion of LOCC-orthogonality (cf. \[ [14] \]). One says that \( \varrho' \) is LOCC-orthogonal, if by LOCC Alice and Bob can transform \( \sum_i p_i |i\rangle_A |i\rangle_B \) into \( |0\rangle_A |0\rangle_B \) or vice versa; \( |i\rangle_A \) is the basis of Alice’s ancilla. In other words, Alice and Bob are able to correlate the state \( \varrho_i \) to orthogonal states of a local ancilla as well as reset the correlations. Consider a state \( \varrho_{AB} \) that can be LOCC-decomposed, i.e. it is a mixture of LOCC-orthogonal states \( \varrho = \sum_i p_i \varrho_i \). The decomposition suggests a scheme for reversible formation of \( \varrho \). Alice prepares locally the state \( \varrho_{A'AB} = \sum_i p_i |i\rangle_{A'} |i\rangle_{AB} \). This costs \( n_{A'AB} - S(\varrho_{A'AB}) \) bits of information. Conditioned on \( i \), Alice compresses the halves of \( \varrho_i \), and sends them to Bob via a quantum channel. This costs \( \sum_i p_i S(\varrho_B) \) qubits of quantum communication. Then, since the \( \varrho_i \) are LOCC-orthogonal, Alice and Bob can reset the ancilla, and return \( n_{A'} \) bits. One then finds, in this protocol, formation costs \( n_{AB} - S(\varrho_{AB}) \) bits, hence it is reversible. Consequently \( E_r \leq \sum_i p_i S(\varrho_B) \), hence

\[ E_r(\varrho_{AB}) \leq \inf_{X=A,B} \sum_i p_i S(\varrho_X), \quad X = A, B \] (5)

where the infimum runs over all LOCC-orthogonal decompositions of \( \varrho_{AB} \).

We can also estimate \( I_f \) by observing that the optimal decomposition for entanglement cost is compatible with LOCC-orthogonal decompositions, i.e. it is of the form \( \{ p_i q_{ij}, \psi_{ij} \} \) where \( \sum_i q_{ij} |\psi_{ij}\rangle = \varrho_i \). Now, Alice prepares locally the state \( \varrho_{A'AB} = \sum_i p_i q_{ij} |i\rangle_{A'} |i\rangle \otimes |j\rangle_{AB} \otimes |\psi_{ij}\rangle \). Conditional on \( ij \), Alice compresses the halves of \( \psi_{ij} \)’s and sends them to Bob. This costs on average \( E_c \) qubits of communication. So far Alice borrowed \( n_{A'AB} - S(\varrho_{A'AB}) \) bits. Alice and Bob then reset and return ancilla \( A' \) (this is possible due to LOCC-orthogonality of \( \varrho_i \)) and also return ancilla \( A'' \) without resetting. The amount of bits used is \( n_{AB} - (S(\varrho_{AB}) - \sum_i p_i S(\varrho_i)) \), giving

\[ \Delta_f \leq \inf \sum_i p_i S(\varrho_i) \leq S(\varrho) \] (6)
show by example, that this may be a very cheap scenario. Thus a regime above the bounds are tight. There is a question, whether by some sophisticated collective scheme, one can do better. We conjecture that it is not the case, supported by the remarkable result of [13]. The authors show that an ensemble of nonorthogonal states cannot be compressed to less than $S(\rho)$ qubits even at the expense of classical communication. In our case orthogonality is replaced by LOCC-orthogonality, and classical communication by resetting. We thus assume equality in Eqs. [14, 16]. Thus for a state that is not LOCC-decomposable (this holds for all two qubit states that do not have a product eigenbasis) we have $\Delta_f = S(\rho_{AB})$, $E_r = \min\{S(\rho_A), S(\rho_B)\}$.

Having fixed two extremal points of our curves, let us see if there is a protocol which is better than the probabilistic one (a straight line on the diagram). We will show by example, that this may be a very cheap scenario. Consider

$$\rho = p|\psi_+\rangle\langle\psi_+| + (1-p)|\psi_-\rangle\langle\psi_-|, \quad p \in \left[0, \frac{1}{2}\right] \quad (7)$$

with $\psi_\pm = \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle)$. When $p \neq 0$ we have $E_r = 1$, $I_f = 2$, $E_c = H(\frac{1}{2} + \sqrt{p(1-p)}) \frac{21}{2}$ where $H(x) = -x \log x - (1-x) \log(1-x)$ is the binary entropy; thus our extreme points are $(1, 2 - H(p))$ and $(E_c, 2)$. For $p = 0$ the state has $\Delta = 0$ hence the formation curve is just a point. We can however plot it as a line $I = 1$ (increasing $Q$ will not change $I$). Now, we decompose the state as $\rho = 2pq_\alpha + (1-2p)|\psi_\alpha\rangle\langle\psi_\alpha|$, where $q_\alpha$ is an equal mixture of LOCC-orthogonal states $|00\rangle$ and $|11\rangle$. The intermediate point is then $(1-2p, 2p - 2)$. A family of diagrams with changing parameter $p$ is plotted in Fig. [3]. The derivative $\chi(Q) = \frac{\partial E}{\partial p}$ has a singularity at $p = 1/2$. Thus we have something analogous to a second order phase transition. The quantity $\chi(Q)$ may be analogous to a quantity such as the magnetic susceptibility. The transition is between states having $\Delta = 0$ (classically correlated) [3] and states with $\Delta \neq 0$ which contain quantum correlations. It will be interesting to explore these transitions and diagrams further, and also the trade-off between information and quantum communication. To this end, the quantity $\Delta_f(Q) + Q - E_c$ appears to express this tradeoff. Finally, we hope that the presented information theory, known as the thermodynamics of entanglement [14, 16, 17].
