ABSTRACT
After at least six years of quiescence, anomalous X-ray pulsar (AXP) 4U 0142+61 entered an active phase in 2006 March that lasted several months and included six X-ray bursts as well as many changes in the persistent X-ray emission. The bursts, the first seen from this AXP in >11 yr of Rossi X-Ray Timing Explorer monitoring, all occurred in the interval between 2006 April 6 and 2007 February 7. The burst durations ranged from $(0.4–1.8) \times 10^3$ s. The first five burst spectra are well modeled by blackbodies, with temperatures $kT \sim 2–9$ keV. However, the sixth burst had a complicated spectrum that is well characterized by a blackbody plus two emission features whose amplitude varied throughout the burst. The most prominent feature was at 14.0 keV. Upon entry into the active phase, the pulsar showed a significant change in pulse morphology and a likely timing glitch. The glitch had a total frequency jump of $(1.9 \pm 0.4) \times 10^{-7}$ Hz, which recovered with a decay time of $17 \pm 2$ days by more than the initial jump, implying a net spin-down of the pulsar. Within the framework of the magnetar model, the net spin-down of the star could be explained by regions of the superfluid that rotate slower than the rest. The bursts, flux enhancements, and pulse morphology changes can be explained as arising from crustal deformations due to stresses imposed by the highly twisted internal magnetic field. However, unlike other AXP outbursts, we cannot account for a major twist being implanted in the magnetosphere.

Key words: pulsars: individual (4U 0142+61) – stars: neutron – X-rays: bursts – X-rays: stars

1. INTRODUCTION

It is now generally accepted that the class of objects referred to as “anomalous X-ray pulsars” (AXPs) are magnetars—young isolated neutron stars powered by the evolution of their high magnetic fields (Thompson & Duncan 1995, 1996). AXPs are X-ray pulsars with periods in the range 2–12 s and X-ray luminosities $(\sim 10^{35}–10^{39}$ erg s$^{-1}$) that cannot be accounted for by their available spin-down energy. The magnetar model was first proposed to explain the dramatic behavior exhibited by an apparently different object class—the soft gamma repeaters (SGRs). SGRs show persistent properties similar to AXPs, but they were first discovered by their enormous bursts of soft gamma rays (>$10^{39}$ erg) and their much more frequent, shorter, and thus less energetic bursts of hard X-rays. To date, SGR-like X-ray bursts have been observed from six AXPs, thus solidifying the connection between the two source classes (Gavriil et al. 2002; Kaspi et al. 2003; Woods et al. 2005; Krimm et al. 2006; Mereghetti et al. 2009; Kumar & Safi-Harb 2011). For reviews of magnetar candidates and AXPs, see Woods & Thompson (2006), Kaspi (2007), and Mereghetti (2008).

Thus far, only the magnetar model can explain the bursts observed from SGRs and AXPs (Thompson & Duncan 1995). The internal magnetic field exerts stresses on the crust which can lead to large-scale rearrangements of the external field, which we observe as giant flares. If the stress is more localized, then it can fracture the crust and displace the footpoints of the external magnetic field which results in short X-ray bursts. The highly twisted internal magnetic field also slowly twists up the external field; magnetospheres of magnetars may therefore be globally twisted (Thompson et al. 2002). Reconnection in this twisted magnetosphere has also been proposed as an additional mechanism for the short bursts (Lyutikov 2002).

In addition to bursts, AXPs and SGRs exhibit pulsed and persistent flux variations on multiple different timescales. An hours-long increase in the pulsed flux has been seen to follow a burst in AXP 1E 1048.1–5937 (Gavriil et al. 2006). On longer timescales, AXPs can exhibit abrupt increases in flux which decay on several-week timescales. These occur in conjunction with bursts and have been suggested as being due to thermal radiation from the stellar surface after the deposition of heat from bursts. Such flux enhancements have been observed in SGRs (see Woods et al. 2001, for example). The flux enhancement of AXP 1E 2259+586 during its 2002 outburst can also interpreted as burst afterglow (Woods et al. 2004), however, a magnetospheric interpretation is also plausible (Zhu et al. 2008). AXP 1E 1048.1–5937 exhibited three unusual flux “flares.” In the first two, the pulsed flux rose on week-long timescales and subsequently decayed back on timescales of months (Gavriil & Kaspi 2004; Tam et al. 2008). These variations have been tentatively attributed to twists implanted in the external magnetosphere from stresses on the crust imposed by the internal magnetic field. AXPs XTE J1810–197, 1E 1547.0–5408, and the AXP candidate AX J1845–0258 have also exhibited large flux variations (Ibrahim et al. 2004; Halpern et al. 2008; Gotthelf & Vasisht 1998; Tam et al. 2006), however it is not clear whether these were of the abrupt rise type as in 1E 2259+586 or the slow-rise type as in 1E 1048.1–5937. CXO J164710.2–455216 showed a clear abrupt rise (Muno et al. 2007). 1RXS J170840.0–313941 exhibited flux “bursts” as well as persistent flux enhancements (Gotthelf et al. 2008). However, it is not clear whether these were of the abrupt rise type as in 1RXS J170840.0–313941 or the slow-rise type as in 1RXS J170840.0–313941. CXE J164710.2–455216 showed a clear abrupt rise (Muno et al. 2007). Finally, AXP 4U 0142+61 has exhibited the longest timescale flux variations thus far, in which the pulsed flux increased by...
29% ± 8% over a period of 2.6 yr (Dib et al. 2007; Gonzalez et al. 2010).

4U 0142+61 is an 8.7 s AXP. It has a period derivative of $\dot{P} = 0.2 \times 10^{-11}$, implying a surface dipole magnetic field of $1.3 \times 10^{14}$ G. 4U 0142+61 was monitored by Rossi X-Ray Timing Explorer (RXTE) in 1997 and from 2000 to 2007. Gavriil & Kaspi (2002) showed that 4U 0142+61 generally rotates with high stability. Morii et al. (2005) reported a possible timing glitch in 1999 on the basis of an Advanced Satellite for Cosmology and Astrophysics (ASCA) observation in which the value of the frequency was marginally discrepant with the frequency as reported by Gavriil & Kaspi (2002). Dib et al. (2007) also reported on the evolution of the properties of 4U 0142+61 from 2000 March to 2006 April. In particular, they reported stable timing and an evolution of the pulse profile in 2–4 keV where the dip between the two peaks was rising between 2000 and 2006. They also reported a 29% ± 8% increase in the pulsed flux between 2002 May and 2004 December. As of 2006 March, in the published flux history of this source, there had been no reports of any X-ray activity such as bursts or flares, as described above for other AXPs.

Here we report on the first detection of bursts from AXP 4U 0142+61, making this the seventh AXP for which this phenomenon has been observed. We also report that the source appears to have entered an active phase in 2006 March in which almost every aspect of the emission changed. Our observations are described in Section 2. Our burst, pulsed morphology, pulse phase, pulsed flux, and timing analysis are presented, respectively, in Sections 3.1, 3.2, 3.3, 3.4, and 3.5. In Section 4, we discuss the possible origins of this behavior and the implications for the magnetar model.

2. OBSERVATIONS

4U 0142+61 has been monitored with RXTE in 1997 and from 2000 to 2007. It has been monitored bi-monthly since 2005 March, with a typical observation length of ~5 ks. On 2006 March 23, the source entered an active phase where many pulsed flux, spectral, and pulse profile changes were observed. We detected six bursts in three observations after the entry into the active phase. After each burst detection, several RXTE target-of-opportunity (ToO) observations were made in addition to the regular monitoring.

Here, we present a detailed analysis of the three observations containing bursts (see Table 1). We also present an analysis of 91 other observations spanning the 2005 March 21 to 2007 May 15 time period (MJD 53481 to MJD 54235, ObsIDs 91070-05-04-00 to 92006-05-32-00). Thirty-two of these observations were prior to the entry into the active phase, and the remaining 59 observations were after. This long-term analysis was performed in order to track the evolving pulsed flux and timing properties of the source.

Figure 1 shows a timeline of the 94 analyzed observations. Note that two segments of any observation that was split counted as separate observations if the segments were given different ObsIDs. The ranges of epochs with an increased density of observations contain the ToO observations. Prior to the active phase, the groups of observations referred to by capital letters in the figure have similar total integration times. The groups of observations in the active phase have similar pulse profiles. These groups will be referred to in Sections 3.2 and 3.5.

3. ANALYSIS AND RESULTS

All data presented here are from the Proportional Counter Array (PCA; Jahoda et al. 2006) aboard RXTE. The PCA is made up of five identical and independent Proportional Counter Units (PCUs). Each PCU is a Xenon/methane proportional counter with a propane veto layer. The data were collected in either GoodXenonwithPropane or GoodXenon mode which record photon arrival times with ~1 μs resolution and bins them with 256 spectral channels in the ~2–60 keV band. For all RXTE observations of 4U 0142+61, photon arrival times at each epoch were adjusted to the solar system barycenter using the position obtained by Patel et al. (2003) from Chandra X-Ray Observatory data.

3.1. Burst Analysis

For each monitoring observation of 4U 0142+61, using software that can handle the raw telemetry data, we generated 31.25 ms light curves using all Xenon layers and events in the 2–20 keV band. These light curves were searched for bursts using our automated burst search algorithm introduced in Gavriil et al. (2004), but we repeat them here as some required modification in order address the distinct properties of these bursts.

To analyze these bursts, we created event lists in FITS format using the standard FTOOLS. For consistency with previous analyses of SGR/AXP bursts, we extracted events in the 2–60 keV band. The burst light curves are displayed in Figure 2 (left). Our techniques for characterizing the temporal and spectral properties of bursts were discussed in detail in Gavriil et al. (2004), but we repeat them here as some required modification in order address the distinct properties of these bursts.

Notes.

a One PCU switched on and another one off part way through the observation, but the total number of active PCUs stayed constant throughout the observation.

b All quoted errors represent 1σ uncertainties. In the fits, the column density was held fixed at \(N_H = 0.64 \times 10^{22} \text{cm}^{-2}\) (Durant & van Kerkwijk 2006b).

c Time of burst peak.

d Rise time.

e These parameters were obtained by fitting the model given by Equation (1) to the burst.

f Short-term decay time of the tail of the burst.

g Long-term decay time of the tail of the burst.

h 2–60 keV peak flux.

i All quoted fluxes and fluences in CGS units are unabsorbed.

j 2–60 keV flux in the tail component of the burst.

k 2–60 keV fluence. These values were obtained by using Equation (2).

l \(T_0\) duration, defined as the time it took to collect 90% of the total burst fluence. These values were obtained by using Equation (3).

m The phases are relative to the template shown in Figure 7.

n Blackbody temperature. For burst 6, the temperature is that of the blackbody component after accounting for the apparent spectral features (see Section 3.1.2).

o The blackbody radius was calculated assuming a distance to the source of 3.5 kpc (Durant & van Kerkwijk 2006a).
p Reduced \(\chi^2\) for the spectral fits.

Before measuring any burst parameters, we determined the instrumental background using the FTOOL pcabackest. We extracted a background model light curve using the appropriate energy band and number of PCUs. pcabackest determines the background count rate only on 16 s time intervals, so we interpolated these values by fitting a polynomial of order six to the entire observation, which yielded a good fit for each data set.

3.1.1. Burst Temporal and Energetic Properties

The burst peak time \(t_p\) was determined using the method described in Gavriil et al. (2004, 2006). Usually, to measure the fluence for SGR and AXP bursts, we subtract the instrumental background for the light curve, integrate the light curve and fit the result to a step function with a linear term whose slope is the “local” background rate. The burst fluence in this case is the height of the step function. Although this technique worked well for the first burst, which was a short, isolated event, it was not appropriate for bursts 2, 3, and 4 because they had overlapping tails, and bursts 4, 5, and 6 had tails that extended beyond the end of the observation. Thus, we opted to determine the best-fit burst profile, \(f(t)\), consisting of exponential rises and decays,

\[
f(t) = \begin{cases} 
  f_p e^{-(t-t_p)/\tau_r} + b(t) + B & t \leq t_p \\
  (f_p - f_e) e^{-(t-t_p)/\tau_f} + f_t e^{-(t-t_p)/\tau_t} + b(t) + B & t > t_p 
\end{cases}
\]

via maximum likelihood testing. The burst peak time \(t_p\), and the background model \(b(t)\) determined using pcabackest, and the “local” background \(B\) were held fixed at the values determined by the methods outlined above. We fit for the rise time \(\tau_r\), the peak flux \(f_p\), the flux of the long-term
tail component \((f_t)\), and for the short-term \((\tau_f)\) and long-term \((\tau_l)\) decay times of the tail of the burst. Figure 2 (left) shows our observed and model burst light curves. The binning was chosen such that the flux in the peak bin was equal to the flux determined from our maximum likelihood fits. We then integrated our events to obtain fluence light curves. Figure 2 (right) shows our observed and model burst fluence time series. For both figures, the contribution from neighboring bursts has been subtracted.

As is done for \(\gamma\)-ray bursts and SGR and AXP bursts, we characterized the burst duration by \(T_{90}\), the time when 90% of the total burst fluence has been collected. From Equation (1) it follows that the total fluence, \(F_{\text{tot}}\), is given by

\[
F_{\text{tot}} = f_p \tau_p + (f_p - f_l) \tau_f + f_l \tau_l,
\]

and the \(T_{90}\) duration is given by

\[
T_{90} = \tau_l \log(10 f_l \tau_l / F_{\text{tot}}).
\]

Although Equation (2) is exact, Equation (3) is an approximation that holds very well because \(T_{90} \gg \tau_f, \tau_l\) for all bursts. This fact is made obvious by Figure 2 (right). All burst temporal parameters are presented in Table 1.

### 3.1.2. Burst Spectral Properties

Burst spectra were extracted using all the counts within their \(T_{90}\) interval. We then filtered the spectra to include counts only from the Xenon layers and from all active PCUs other than PCU 0. PCU 0 was ignored because of the loss of its propane layer and due to its frequent breakdowns. Background intervals were extracted from long, hand-selected, featureless intervals prior to the bursts. Response matrices were created using the FTOOL \texttt{gcisresp}. The burst spectra were grouped such that there were at least 10 counts per bin after background subtraction. Burst spectra, background spectra, and response matrices were then read into the spectral fitting package \texttt{XSPEC}\(^6\) v12.3.1. The spectra were fit to photoelectrically absorbed blackbodies using the column density found by Durant & van Kerkwijk (2006b). Only bins in the 2–30 keV band were included in the fits. The blackbody model provided an adequate fit for bursts 1 through 5; model parameters are presented in Table 1.

Extracted over its very long \(T_{90}\) interval (see Table 1), the spectrum of burst 6 was well fit by a simple blackbody, however there were hints of spectral features. On much shorter timescales, the spectrum of burst 6 was not well modeled by any simple continuum model and the presence of spectral features is clear (see Figure 3). We looked closely at the first 8.69 s (one pulse period) of the burst (see Figure 3), and determined that a simple continuum model with less than two spectral features was not a statistically good representation of the data. A simple photoelectrically absorbed blackbody yielded a reduced \(\chi^2\) of 2.1 for 39 degrees of freedom (dof). Adding a single Gaussian emission line improved the fit but not sufficiently, yielding reduced \(\chi^2\)s of 1.3 for 36 dof. Only a photoelectrically absorbed blackbody plus two Gaussian emission lines provided

\[\text{http://xspec.gsfc.nasa.gov}\]
Figure 3. Panel 1a: the spectrum of burst 6 extracted over a pulse period (8.69 s) starting 50 ms before the burst peak. The red solid lines represents the best-fit model—a photoelectrically absorbed blackbody (red curve). The fit had a reduced $\chi^2$ of 2.1 for 39 degrees of freedom (dof). Panel 1b: the difference between the data and the model shown in panel 1a, divided by the uncertainty. Panels 2a and 2b: same, except here the best-fit model (red curve) consists of a blackbody (dashed blue curve) plus a two Gaussian emission lines (dashed green curve), all photoelectrically absorbed. The fit had a reduced $\chi^2$ of 1.3 for 36 dof. Panels 3a and 3b: same, except here the best-fit model (red curve) consists of a blackbody (blue curve) plus a two Gaussian emission lines (dashed green curves), all photoelectrically absorbed. The fit had a reduced $\chi^2$ of 1.1 for 34 dof.

(A color version of this figure is available in the online journal.)

We investigated whether different continuum models could describe the feature-rich burst spectrum just as well as a blackbody. We tried a simple power-law model, as well as more complicated continuum models such as a cutoff power law (PLCUT; White et al. 1983) and a negative/positive exponential (NPEX; Mihara 1995). The PLCUT and NPEX models are often used to fit the continuum component of the line-rich spectra of accreting X-ray pulsars (see Coburn et al. 2002). All three of our alternate continuum models also required two emission features at similar energies as the blackbody, however they did not provide improved fits. The best alternative to a blackbody was the PLCUT model with two Gaussian emission lines at 8.8 and 14.3 keV with reduced $\chi^2 = 1.1$ for 33 dof. Note how this model combination had the same reduced $\chi^2$ as the blackbody combination, but required one more free parameter.

To study the temporal evolution of these features, we extracted 17.38 s (two pulse periods) long spectra in steps of 4.34 s (half a pulse period) from the peak of the burst and repeated the spectral fitting procedure outlined above. Figure 4 displays the spectral evolution of the features. The middle panel is a surface plot of the change in $\chi$ after subtracting the continuum model (blackbody). A vertical slice in the middle panel corresponds to a spectrum of the burst extracted over a two-pulse-period long interval, and these spectra were extracted in time steps of half a spin period. The features showed clear temporal variability and were most prominent near the onset of the burst (see Figure 4). From the surface plot in Figure 4 (middle panel), we see that the 14.2 keV is highly significant at the start of the burst and remains detectable at the $>1\sigma$ level for $\sim 130$ s. The significance of the features at similar energies as the blackbody, however they did not provide improved fits. The best alternative to a blackbody was the PLCUT model with two Gaussian emission lines at 8.8 and 14.3 keV with reduced $\chi^2 = 1.1$ for 33 dof. Note how this model combination had the same reduced $\chi^2$ as the blackbody combination, but required one more free parameter.

We then determined whether the features could be described by absorption rather than emission. We tried three different absorption models: cyclotron absorption, Gaussian absorption (multiplicative model), and simply subtracting Gaussians. We tested all three of these absorption models with all the continuum models described above. No permutation provided a better fit than a blackbody with two emission lines, a simple power-law with two Gaussian absorption lines at 10.8 keV and a broad (Gaussian width $\sigma = 4.4$ keV) feature at 2.5 keV being the best absorption model combination with reduced $\chi^2 = 1.2$ for 33 dof.

To study the temporal evolution of these features, we extracted 17.38 s (two pulse periods) long spectra in steps of 4.34 s (half a pulse period) from the peak of the burst and repeated the spectral fitting procedure outlined above. Figure 4 displays the spectral evolution of the features. The middle panel is a surface plot of the change in $\chi$ after subtracting the continuum model (blackbody). A vertical slice in the middle panel corresponds to a spectrum of the burst extracted over a two-pulse-period long interval, and these spectra were extracted in time steps of half a spin period. The features showed clear temporal variability and were most prominent near the onset of the burst (see Figure 4). From the surface plot in Figure 4 (middle panel), we see that the 14.2 keV is highly significant at the start of the burst and remains detectable at the $>1\sigma$ level for $\sim 130$ s. The significance of the
3.2. Pulse Profile Changes

Many AXP outbursts are accompanied by significant pulse profile changes (e.g., Kaspi et al. 2003). To search for these in 4U 0142+61, for each observation, we generated 64 bin pulse profiles using the method described in Dib et al. (2007). We then aligned the profiles with a high signal-to-noise template using a cross-correlation procedure in the Fourier domain. Then, for each group of observations in the active phase, we summed the aligned profiles, extracted the unpulsed component from the summed profile, and scaled the resulting profile so that the value of the highest bin is unity and the lowest bin is zero.

The resulting pulse profiles are shown in Figure 5 in chronological order. The panels in the leftmost column are from Dib et al. (2007) and show pulse profiles in the six years prior to the entry into the active phase. Note the slow change in the height of the dip between the peaks. The panels in columns 2 and 3, marked with the corresponding letter in the top right corner, show pulse profiles for each of the data groups in the active phase that were marked with a letter in Figure 1. The four plots in bold correspond to the observations marked with “x,” “b1,” “b2,” and “b3” in Figure 1.

The pulse profile evolution can be described as follows: prior to the active phase, features in the double-peaked pulse profile were evolving on a timescale of several years (see panels C6–C10 corresponding to RXTE Cycles 6–10). Then, in the first observation of the active phase (panel x), the pulse profile became suddenly triple-peaked. It was also triple-peaked in the following observation (panel b1), in which a burst occurred. It remained multi-peaked for the following two groups of observations (panels G and H). Then, an observation with multiple bursts occurred (panel b2). In that observation, also having a triple-peaked pulse profile, the middle peak was taller than the other two. Following this observation, the pulse profile seemed to be slowly recovering back to its double-peaked
Figure 5. Pulse profile evolution of 4U 0142+61. Left column: normalized average 2–10 keV pulse profiles in the six years prior to the entry into the active phase in chronological order (panels from Dib et al. 2007). Middle and right columns: normalized, averaged 2–10 keV pulse profiles for each of the data groups marked by a letter in Figure 1, after the entry into the active phase. The four plots with bold labels correspond to the observations marked with “x,” “b1,” “b2,” and “b3” in Figure 1.

We also performed an analysis of the Fourier components of the pulse profiles. The results are shown in Figure 6. The variations in the power of the fundamental Fourier component are shown in panel 1, and that of the second harmonic is in panel 2. Note how the amplitude of the fundamental varied monotonically prior to, but not during, the active phase. Also note how the power in the second harmonic was already back to its pre-active-phase level before the last burst occurred.

3.3. Burst Rotational Phases

An important factor in understanding the origin of the bursts is the rotational phase at which they occur. The phases of the bursts are shown in Figure 7. For each burst observation, we created at 31.25 ms time resolution light curve and folded it using our timing solution (see Section 3.5). We then phase-aligned these folded profiles by cross-correlating them with the long-term pulse profile template. Our phase-aligned folded profiles are shown in Figure 7 (histograms in the last row). Superposed on each folded profile are two curves. The top curve is made of the...
Figure 6. Top: evolution of the power in the fundamental Fourier component of the pulse profile of 4U 0142+61 in the 2–10 keV band. Bottom: evolution of the power in the second harmonic. In both panels, the points with large horizontal error bars are from Dib et al. (2007). The remaining points are obtained from groups of observations after the entry into the active phase. The three bold points correspond to the observations with bursts. The three dashed lines correspond to burst epochs.

Figure 7. Phase analysis of the six detected bursts. Each column corresponds to an observation in which bursts were detected. Top row: 200 s segments of the time series containing the bursts in the 2–20 keV band. The time resolution is 1 s. Middle row: 4 s segments of the time series containing the bursts. The time resolution 31.25 ms. Bottom row: aligned folds of the burst observations shown below the scaled long-term average profile. The folded counts are presented as histograms. Superposed on each histogram are two curves. The top curve is made of the five Fourier harmonics that best fit the histogram. The bottom curve is made of the best-fit five harmonics after the removal of the 4 s centered on each burst. The arrows indicate the phases of each burst.
Figure 8. rms pulsed flux within the observations containing bursts. Each column corresponds to one observation. In each column we show, descending vertically, the 1 s resolution light curve with the bursts indicated, the 2–4 keV rms pulsed flux, and the 4–20 keV rms pulsed flux. The dotted line in each of the pulsed flux plots shows the average of the pulsed fluxes obtained after segmenting and analyzing the time series of the observation immediately prior to the one shown.

The first three bursts occurred near the middle “new” peak in the profile. Burst 5 occurred near the old tall peak of the profile (see Figure 5). The phase of burst 6 corresponds again to a new peak in the profile, this time located where the previous small peak used to be. The coincidences of several bursts with new, transient profile features that are present even when the actual burst data are removed are suggestive of lower-level transient emission from the same physical location, with the burst being the extreme of this emission’s luminosity distribution.

3.4. Pulsed Flux Analysis

3.4.1. Short-term Pulsed Flux Analysis

Previous AXP bursts are often accompanied by short-term pulsed flux enhancements (e.g., Gavriil et al. 2006). To search for these, for each of the three observations containing bursts, we made two time series in count rate per PCU, one for the 2–4 keV band and the other for 4–20 keV. We included only photons detected by PCUs that were on for the entire duration of the observation. The time resolution was 31.25 ms. We removed the 4 s centered on each burst from each time series. Then, we broke each time series into segments of length ∼500 s. For each segment, we calculated the pulsed flux using two different methods.

First, we calculated the rms pulsed flux using

$$F_{\text{rms}} = \sqrt{\frac{1}{n} \sum_{k=1}^{n} (a_k^2 + b_k^2) - (\sigma_{a_k}^2 + \sigma_{b_k}^2)},$$

where $a_k$ is the $k$th even Fourier component defined as $a_k = \frac{1}{N} \sum_{i=1}^{N} p_i \cos(2\pi ki/N)$, $\sigma_{a_k}$ is the uncertainty of $a_k$, $b_k$ is the $k$th odd Fourier component defined as $b_k = \frac{1}{N} \sum_{i=1}^{N} p_i \sin(2\pi ki/N)$, $\sigma_{b_k}$ is the uncertainty of $b_k$, $i$ refers to the phase bin, $N$ is the total number of phase bins, $p_i$ is the count rate in the $i$th phase bin of the pulse profile, and $n$ is the maximum number of Fourier harmonics to be taken into account; here $n = 5$ for consistency with Dib et al. (2007) and Gonzalez et al. (2010).

While least sensitive to noise compared to other pulsed flux measurement methods, the rms method returns a pulsed flux number that is affected by pulse profile changes. To confirm our pulsed flux results, we also used an area-based estimator to calculate the pulsed flux:

$$F_{\text{Area}} = \frac{1}{N} \sum_{i=1}^{N} p_i - p_{\text{min}},$$

where $p_{\text{min}}$ is the average count rate in the off-pulse phase bins of the profile, determined by cross-correlating with a high signal-to-noise template, and calculated in the Fourier domain after truncating the Fourier series to five harmonics. The results are shown in Figure 8 for $F_{\text{rms}}$ ($F_{\text{Area}}$ gives consistent results). Note the significant increase in the 4–20 keV pulsed flux in the 2006 June observation following the cluster of bursts. This increase is not present in 2–4 keV. Also note the significant rise and subsequent decay of the pulsed flux following the large 2007 February burst. The pulsed flux was sufficiently enhanced in these two observations that one can see individual pulsations by eye in Figure 7 in the two panels marked with a star, containing the raw burst light curves with 1 s time resolution.

3.4.2. Long-term Pulsed Flux Analysis

For each of the 94 analyzed observations, we created a pulse profile (in units of count rate per PCU) using the same procedure as in Section 3.2. Then, we calculated the pulsed flux for each observation using Equations (4) and (5). Data from PCU 0 were
omitted because the long-term trend in the pulsed counts is not the same as that in the remaining PCUs, presumably due to the loss of its propane layer. Data from PCU 1 were omitted after the loss of its propane layer as well, on MJD 54094.

We extracted pulsed fluxes in the 2–4 and 4–20 keV bands using both the rms and area pulsed flux method because of the numerous pulse profile changes around the times of the bursts. There is no evidence of a long-term change in the pulsed flux associated with the bursts except, possibly, for a hint of an increase in the 2–4 keV band roughly midway between the second and third observations containing bursts. We also note that the 4–20 keV pulsed flux of two of the observations containing bursts are significantly larger than the long-term average. Removing the bursts from these observations does not change this result.

We performed the same analysis for individual observations in 2–10 keV for an extended period of time. This is shown in panels 2 and 3 of Figure 9. This plot is an update to Figure 10 of Dib et al. (2007).

In order to verify that trends seen in panels 2 and 3 of Figure 9 are not an artifact of the evolution of the response of the detector, we calculated the pulsed flux in erg s$^{-1}$ cm$^{-2}$ using a method that took the evolution of the response into account. The method is described in Dib et al. (2007) and takes into account spectral fits obtained from imaging data (in this case XMM data, see Gonzalez et al. 2010) to convert counts to energy for each combined set of observations. For this analysis, we used data from all PCUs; however, data from PCU 1 were excluded after the loss its propane layer. Data from PCU 0 were included because the response matrices used took into account the loss of its propane layer.

The results are shown in panel 1 of Figure 9. The first six points, corresponding to RXTE Cycles 6–10, are from Dib et al. (2007). The second to last point is obtained by combining all observations that occurred between bursts 1 and 2, but omitting observations containing bursts. The observations that we included took place during the exponential recovery of the possible glitch (see Section 3.5). The last point in panel 1 was obtained by combining the observations that occurred after burst 2, but again omitting those containing bursts. The observations we included took place after the end of the exponential recovery of the possible glitch (see Section 3.5).

In the first of the two data points in the active phase, the pulsed flux in erg s$^{-1}$ cm$^{-2}$ is 18% ± 8% larger than in the pre-active phase. This is consistent with the increase reported in Gonzalez et al. (2010) in the same energy range. A hint of this increase can be seen in panel 2 although it appears less significant. This discrepancy can be accounted for by the fact that the spectrum changed: Gonzalez et al. (2010) reported a temporary increase in the spectral hardness in an XMM observation of 4U 0142+61 immediately following the bursts.

3.4.3. Combined Pulse Morphology and Pulsed Flux Analysis

In Section 3.2, we calculated the Fourier components of the aligned average pulse profiles. This gave us the relative amplitude of the pulse profile harmonics in each group of observations marked with a letter in Figure 1. In Section 3.4.2, we calculated the pulsed flux for every observation. Here, we compute a weighted average of the pulsed flux for each group of observations using the flux points calculated in Section 3.4.2. We then reconstruct the profiles for each of the groups from the first five Fourier components (not including the unpulsed component), scale them by the average rms pulsed flux for that group, and add the necessary offset for the lowest point on each curve to be zero. This means that the resulting scaled profiles return the correct pulsed flux. The advantage of this analysis is that we can now trace the evolution of each of the peaks independently.

The results are presented in Figure 10. In panel (a), we show the average scaled pulse profile per observation for observations in the year preceding the active phase. The profile is double-peaked. In panel (b), we show in bold the scaled profile for the observation containing burst 1. We also show the scaled profiles in each of the groups of observations that followed the burst. The profiles are triple-peaked. In panel (c), we show in bold the scaled profile for the observation containing bursts 2, 3, 4, and 5. We also show the scaled profiles in each of the groups of observations that followed the bursts. Note how the increase in the pulsed flux in the observation containing the bursts is not only a consequence of the appearance of the new peak, but a result of the increase in size of all three peaks. Also note the evolution of the pulse profile back to being double-peaked. In panel (d), we show in bold the scaled profile for the observation containing burst 6. We also show the scaled profiles in each of the groups of observations that followed the burst. Note again how the pulse flux increase is due to both peaks increasing in size.

3.5. Timing Analysis

Many AXP outbursts and active phases are accompanied by interesting timing anomalies (e.g., Kaspi et al. 2003; Woods
et al. 2004; Israel et al. 2007a; Dib et al. 2009). Next we consider the timing behavior of 4U 0142+61, which, as we show, also exhibits interesting evolution at the start of the active phase.

For all our RXTE observations of 4U 0142+61, we created 31.25 ms time resolution light curves, including only the events in the energy range 2.5–9 keV to maximize the signal-to-noise ratio of the pulse. Each binned time series was epochfolded using an ephemeris determined iteratively by maintaining phase coherence; see below. Resulting pulse profiles, with 64 phase bins, were cross-correlated in the Fourier domain with a high signal-to-noise template created by adding phase-aligned profiles from all observations. The cross-correlation returned an average pulse time of arrival (TOA) for each observation corresponding to a fixed pulse phase. The pulse phase $\phi$ at any time $t$ can be expressed as a Taylor expansion,

$$
\phi(t) = \phi_0(t_0) + v_0(t - t_0) + \frac{1}{2} \ddot{v}_0(t - t_0)^2 + \frac{1}{6} \dddot{v}_0(t - t_0)^3 + \ldots,
$$

where $v \equiv 1/P$ is the pulse frequency, $\dot{v} \equiv dv/dt$, etc., and subscript “0” denotes a parameter evaluated at the reference epoch $t = t_0$. To obtain ephemerides, the TOAs were fitted to the above polynomial using the pulsar timing software package TEMPO.\footnote{See http://www.atnf.csiro.au/research/pulsar/tempo.}

As explained above, our first set of TOAs was obtained by aligning the folded observations with a template profile using a cross-correlation procedure. In order to determine to what extent this set of TOAs was affected by the pulse profile changes that took place in the active phase, we generated two additional sets of TOAs (sets 2 and 3).

For set 2, we made the assumption that the location of the trough of the pulsations, determined by finding the minimum in the pulse profile after smoothing, is not affected by the pulse profile changes. We then generated TOAs by aligning the pulsation trough of the folded observations with that of the template and extracting phase differences. The last set of TOAs (set 3) was obtained after aligning the tallest peak of each smoothed pulse profile with that of the long-term template. All three sets of TOAs are provided as a machine readable table in the electronic edition. A portion of the table starting from the active phase is provided in Table 3.

Timing residuals for all three sets of TOAs are shown in Figure 11 using two different ephemerides. The linear ephemeris used in the top panel is the ephemeris that best fit the first set of TOAs prior to the active phase. The linear ephemeris used in the bottom panel is that obtained by fitting the first set of TOAs in the regions indicated by the horizontal arrows, with a phase jump in between. The same long-term trend is present in the first two sets of timing residuals, with more scatter in the second set. The difference in phase between each bold circle and the corresponding empty circle represents our uncertainty in determining a fiducial point on the pulsar. In the third set of residuals, the outlier points represent the observations where the largest peak was no longer the rightmost peak. Apart from the outliers, the same trend seen in the other two sets of residuals is present in the third set.

From here on, we assume that the presence of the same trend in our three sets of residuals is an indication that the TOAs in the first set were not significantly affected by the pulse profile changes. We therefore have used the first set of TOAs (one for each of the 94 observations) in the remainder of this section.

Using the above assumption, the results of the timing analysis are shown in Figure 12. The results of a segmented timing analysis are in panels 1 and 2. The results of a long-term timing analysis are in panels 3, 4, 5, and 6 of the same figure.

For the segmented timing analysis, we used the 70 TOAs that had the smallest uncertainties (indicated in the online version of Table 3) and omitted the TOAs of the three burst observations as well as the TOA of the first observation in the active phase. We then divided the data into segments of similar pulse profiles. For each data segment, we found a linear ephemeris using TEMPO.\footnote{For the segmented timing analysis we ran TEMPO in mode 1.}

We plotted the resulting ephemerides in panel 1 of Figure 12 with the uncertainties returned by TEMPO. The timing residuals are shown in panel 2. Note how the slope between bursts 1 and 2 is more negative than the long-term average.

We then fit a linear trend through all the pre-burst observations, and another linear ephemeris through the post-burst observations after the pulse profile had started to return to the double-peaked shape. We did not include the TOA corresponding
Figure 11. Top: timing residuals for all three sets of TOAs. Bold circles: timing residuals obtained using the first set of TOAs obtained by cross-correlation in the Fourier domain. Empty circles: residuals obtained using the second set of TOAs obtained by aligning the off-pulse regions of the pulse profiles. Triangles: residuals obtained using the third set of TOAs obtained by aligning the tallest peak of the pulse profiles. The linear ephemeris used to produce all three sets of residuals is that which best fit the first set of TOAs in the pre-active phase region. Bottom: timing residuals for the same three sets of TOAs. The linear ephemeris used is that which best fit the first set of TOAs exclusively in regions indicated with the horizontal arrows with an arbitrary phase jump in the gap between the arrows. The phase residuals are relative to the linear ephemeris (ignoring the phase jump) and vertically offset such that the average phase residual is zero. Both panels: the dotted line indicates the epoch of the first observation of the active phase. The dashed lines indicate the burst epochs.

Notes.

- TOA number. TOA number 33 is the first observation in the active phase. TOAs number 34, 58, and 78 represent the first, second, and third observation containing bursts.
- RXTE observation identification number.
- Total exposure.
- The effective number of PCUs on during the observation.
- Barycentered pulse TOA. Set corresponds to the TOAs obtained by cross-correlating the folded pulse profiles with a high signal-to-noise template. Sets 2 and 3 are similar to set 1; however, we constrained our cross-correlation to the trough and peak of the pulsations, respectively. See Section 3.5 for details.
- Uncertainty on TOA for sets 1, 2, and 3.
- Whether the TOA was included in the partial timing analysis. Note: all TOAs were included in the long-term analysis.

(This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.)

to the last observation containing bursts. The results are plotted in panel 3 of Figure 12 with uncertainties, with the residuals in panel 4. Note the difference in the slope in the two regions. In particular, extrapolating the two ephemerides to a point between their times of validity makes it seem like a sudden spin-down, i.e., an “anti-glitch” occurred.

Finally, we included all the TOAs and did one global fit. In order to provide a good fit to the TOAs at the onset of the active
With the glitch model consisting of a permanent change in phase, we had to assume that a glitch occurred on MJD 53809, as shown in Figure 12. Panel 1: frequency vs. time plot of local linear ephemerides with uncertainties. The linear trend corresponding to the local ephemeris directly before the active phase is subtracted from all local ephemerides. Panel 2: timing residuals after subtracting the ephemerides shown in panel 1. Panel 3: frequency vs. time plot (with uncertainties) of the best-fit linear ephemerides in the pre-active phase region and in the post burst 2 region. The same trend as in panel 1 was subtracted. Panel 4: timing residuals after subtracting the ephemerides shown in panel 3. Panel 5: frequency vs. time plot (with uncertainties) of the best-fit long-term ephemerides which includes a glitch at MJD 53809 followed by a fast exponential recovery. The same trend as in panel 1 was subtracted. Panel 6: timing residuals after subtracting the ephemeris shown in panel 5. All panels: the dotted line indicates the epoch of the first observation of the active phase. The dashed lines indicate the burst epochs.

Phase, we had to assume that a glitch occurred on MJD 53809, with the glitch model consisting of a permanent change in $v$ and $\nu$ and a frequency change $\Delta \nu_d$ that recovered exponentially on a timescale $\tau_d$, i.e.,

$$v = v_0(t) + \Delta v + \Delta \nu_d e^{-\frac{t-t_g}{\tau_d}} + \Delta \nu(t-t_g),$$

where $v_0(t)$ is the frequency evolution pre-glitch given by $v_0(t) = v(t_0) + \dot{v}(t-t_0)$, $\Delta v$ is an instantaneous unrecovered frequency jump, $\Delta \nu_d$ is the frequency increase that decays exponentially on a timescale $\tau_d$, $t_g$ is the glitch epoch determined by setting the phase jump to zero, and $\Delta \nu$ is the post-glitch change in the long-term frequency derivative. The values of the fit parameters are listed in Table 4.

From Table 4, we can see that the total sudden change in frequency which happened at the onset of the active phase ($\Delta v_{tot} = \Delta v + \Delta \nu_d$) is positive, and $\Delta \nu_d$ decayed exponentially. At the end of the decay, the net effect of the recovered glitch was a negative $\Delta v$. That is, the data suggest that after $\nu_d$ had decayed, there remained net spin-down relative to the undisturbed ephemeris from before the active phase.

The fit parameter $\Delta \nu_d$, from which we conclude a sudden spin-up, is controlled primarily by the first few TOAs in the active phase. It is therefore possible that it is affected by pulse profile changes. However, as shown in Figure 11, the TOAs in the active phase were not significantly contaminated by pulse profile changes. Also, the segmented analysis shown in Figure 12 clearly indicates an initial spin-up.

In contrast to $\Delta \nu_d$, the fit parameter $\Delta v$, from which we conclude a net spin-down, is primarily controlled by the TOAs outside of the active phase, which were certainly not affected by pulse profile changes (Figure 12, panel 3).

We therefore conclude that the pulsar likely suffered a spin-up glitch near or at the start of the radiatively active phase, but that the glitch “over-recovered” such that long term, its net effect is a spin-down of the pulsar.

| Parameter | Value |
|-----------|-------|
| MJD start | 53481.268 |
| MJD end | 54235.319 |
| TOAs | 93 $^b$ |
| $\nu$ (Hz) | -0.1150920955(12) |
| $\nu_d$ ($10^{-14}$ Hz s$^{-1}$) | -2.661(9) |
| Epoch (MJD) | 53809.185840 |
| Glitch epoch (MJD) | 53809.185840 |
| $\Delta \nu$ (Hz) | $-1.27(17) \times 10^{-8}$ |
| $\Delta \nu_d$ (Hz) | $-3.1(1.2) \times 10^{-16}$ |
| $\Delta \nu_{tot}$ (Hz) | $2.0(4) \times 10^{-7}$ |
| $t_d$ (days) | 17.0(1.7) |
| rms residual (phase) | 0.0168 |

**Notes.**

$a$ Numbers in parentheses are TEMPO-reported 1σ uncertainties.

$b$ A single TOA was omitted due to the very poor signal-to-noise ratio in the corresponding observation.

### 4. DISCUSSION

In this paper, we have described the timing, pulse profile, and pulsed flux behavior of 4U 0142+61, during its 2006–2007 active phase, the first such episode yet studied from this source. Specifically, we have shown that in addition to a sudden departure from a slow, systematic evolution of the source’s pulsed flux and pulse profile, this AXP also suffered a significant timing event that is best described as a sudden spin-up glitch, followed by a large decay of the frequency jump such that the net effect was a slow-down with $\Delta v/v \sim -8 \times 10^{-8}$. Interestingly, the pulsed X-ray flux showed no significant change apart from immediately following bursts, in contrast to other AXP radiative outbursts (e.g., Kaspi et al. 2003; Tam et al. 2008; Ibrahim et al. 2004; Munoz et al. 2007). Further, we have reported on six SGR-like bursts from the source that occurred during this period, one of which was notable for its unusual spectrum, which was poorly fit by an continuum model.

#### 4.1. The SGR-like Bursts from 4U 0142+61

Five of the six bursts reported here for 4U 0142+61 had fast-rise-slow-decay profiles, with tails much longer than the
rise times. These morphologies are similar to the class of AXP bursts labeled as “Type B” by Woods et al. (2005). Type B AXP bursts have also been characterized by arriving preferentially at pulse maximum, and are seen more often in AXPs compared with SGRs (Woods et al. 2005; Gavriil et al. 2006). They were suggested as being due to a sudden rearrangement of magnetic field lines anchored in the crust following a crustal fracture (Thompson & Duncan 1995), as opposed to reconnection events in the upper magnetosphere (e.g., Lyutikov 2002), argued as more likely for the shorter, symmetric “Type A” bursts that show no preference for pulse maximum. However, it is interesting that in the 4U 0142 + 61 bursts, in spite of their B-type morphology, no clear preference for arrival at or near pulse maximum was seen (see Table 1). This may blur somewhat the distinction between the putative types, although the morphological distinction remains clear.

It is also notable that the vast majority of bursts seen from AXPs had long tails following fast rises. An exception is 1E 2259 + 586 for which, during its 2002 outburst, the minority (roughly one dozen out of 80) of the bursts seen were of this form, the majority being of Type A, similar to those classically seen in SGRs, and suggested by Woods et al. (2005) to be magnetospheric. A possible hint regarding the origin of the different types may lie in that 1E 2259 + 586 was mid-outburst when its bursts were observed, whereas the other sources’ bursts all occurred in the days/months following the commencement of an active period, presumably as the pulsar recovered from a major event, rather than mid-event.

### 4.1.1. Spectral Features

The complicated spectrum of burst 6 is puzzling. The most broad feature at ~14 keV is particularly interesting. Emission features at similar energies were observed from two out of the three bursts from 1E 1048.1—5937 (Gavriil et al. 2002, 2006) and in one out of the four bursts from XTE J1810—197 (Woods et al. 2005). We have reanalyzed all these burst spectra consistently as for 4U 0142 + 61. In Figure 13, we plot the spectra of all AXP bursts with likely emission lines in their spectra. Note that all have broad features that occur between 13 and 14 keV. There is also evidence for a narrow feature at ~8 keV in the 4U 0142 + 61 burst; there may be hints of additional features in some of the other burst spectra as well.

If the features are interpreted as of a cyclotron origin, it is puzzling that three sources with spin-down-inferred magnetic fields that span a range of a factor of three produce features at similar energies. The similarity in energy suggests a mechanism that is not very sensitive to the exact value of the magnetic field. Moreover, it is unclear why such features are seen only in some bursts. Cyclotron features have been observed in the persistent spectra of accretion-powered X-ray pulsars (Coburn et al. 2002). Unlike the features observed here, these features can be well fit by a Gaussian absorption model (see Section 3.1.2). In the spectra of some accretion-powered X-ray pulsars, there is also evidence for higher harmonics. The features observed in the 4U 0142 + 61 burst were not consistent with being harmonically related, even after taking into account the relativistic effects on the spacing (see Harding & Daugherty 1991; Araya & Harding 1999).

Thus far, all AXP burst spectral features have been observed with *RXTE*. Their absence from many other *RXTE*-observed bursts, together with the absence of any response feature in the PCA near 13–14 keV, is supporting evidence for their veracity. Nevertheless, it is important to confirm these features with other instruments. Observations of AXPs during active phases using the *Swift XRT* or the large-area LAXPC aboard the planned *Astrosat* mission would be particularly useful in this regard.

### 4.2. The Net Spin-down Event in 4U 0142 + 61

The timing glitch reported on in Section 3.5 had recovery fraction, defined as $Q \equiv \Delta v_{d}/(\Delta v_{d} + \Delta v)$, equal to $1.07 \pm 0.02$. $Q > 1$ implies that the net frequency change after the transients have decayed is negative (see panel 3 of Figure 12 and Table 4). Indeed, the net $\Delta v_{d}$ observed is $-1.1 \pm 0.1 \times 10^{-7}$. Such a $Q > 1$ has not previously been reported in any AXP but has been seen following magnetar-like radiative behavior in one high-$B$ rotation-powered pulsar (Livingstone et al. 2010). Note that Morii et al. (2005) reported a candidate glitch in 1999 from this source. If such a glitch occurred, based on the ephemerides reported in Dib et al. (2007), the fractional frequency change, after any recovery, would have been $+1.9(2) \times 10^{-7}$ to $8.6(2) \times 10^{-7}$ depending on the glitch epoch, but manifestly positive.

In the standard model for glitches in rotation-powered pulsars, the neutron-star crust contains superfluid neutrons that rotate faster than the bulk of the surrounding matter (see, e.g.,
Anderson & Itoh 1975; Anderson et al. 1982; Alpar et al. 1984; Alpar & Pines 1993). This is argued to be a result of the fact that the external magnetic torque acts on the crust and coupled core components only, with the uncoupled superfluid unaffected. The superfluid’s angular momentum resides in quantized vortex lines whose density is proportional to angular velocity. The vortex lines are suggested to be pinned to crustal nuclei and suffer strong forces due to the angular velocity lag that builds between crust and superfluid. A glitch in this picture is a sudden unpinning and outward motion of vortex lines, with a transfer of angular momentum from superfluid to crust. In a magnetar, unpinning may occur due to the strong internal magnetic field as it deforms the crust plastically or cracks it violently (Thompson & Duncan 1996).

In the 4U 0142 + 61 event we describe in Section 3.5, if the standard glitch model is roughly correct and applies here, then some regions of the stellar superfluid were originally spinning slower than the crust. Then the transient increase in frequency would be a result of transfer of angular momentum first from a more rapidly rotating region, with a subsequent angular momentum drain from the crust to a more slowly rotating region. As argued by Thompson et al. (2000), regions of slower-rotating superfluid can occur in magnetars, because the superfluid vortex motions are governed not by spin-down-related forces, but by advection across the stellar surface by the deforming crust. Those authors show that the number of vortex lines per unit surface area of crust can increase or decrease depending on the crustal motion relative to the stellar rotation axis. They invoke this possibility to explain a possible “anti-glitch” seen in SGR 1900+14. However, that event was orders of magnitude larger than the crustal motion relative to the stellar rotation axis. They invoke this possibility to explain the spin-down may thus add to the already large amount of evidence against any accretion-powered origin for 4U 0142 + 61.

### 4.3. The Active Phase of 4U 0142 + 61 and Other AXP Outbursts

In many ways, the 2006–2007 active phase of 4U 0142 + 61 is similar to other phases of activity seen in AXPs: it was punctuated by short bursts, pulse profile changes were seen, and it was accompanied by a significant rotational anomaly. However, the 4U 0142 + 61 activity is unique in one interesting way: the pulsar did not suffer a large, long-lived pulse flux increase at the beginning of the phase. Indeed, its pulsed flux (Figure 9), apart from very near bursts, has remained relatively stable. We note that observations with focusing X-ray telescopes may reveal some phase-averaged flux variations (see Gonzalez et al. 2010); indeed, pulsed fraction has been shown to be inversely correlated with total flux in 1E 1048.1−5937 (Tiengo et al. 2005; Tam et al. 2008), rendering pulsed flux variations smaller relative to total variations. Still, for 4U 0142 + 61, such a correlation would have to conspire to render the pulsed flux steady. This seems unlikely, however only focusing telescope observations can rule this out.

Other AXP radiative outbursts have been suggested as arising from large magnetospheric twists, with associated magnetospheric currents returning to the stellar surface and heating it, resulting in increased X-ray emission from the source (e.g., Thompson et al. 2002; Beloborodov & Thompson 2007; Beloborodov 2009). Such twists are thought to represent a release of magnetic energy and helicity from the internally wound-up magnetic field.

On the assumption that the pulsed flux is a reasonable proxy for the total flux for 4U 0142 + 61, here, we find no clear evidence for significantly increased X-ray emission on timescales longer than a few minutes. Thus, any large-scale magnetospheric twist scenario is problematic. As originally showed by Thompson et al. (2002), the X-ray luminosity due to returning currents reheating the surface in a significantly twisted magnetosphere in general are comparable to that produced from internal processes; this is clearly not observed in the 2006–2007 active period of 4U 0142 + 61.

Instead, for this source, long-term evolution of the crust, driven presumably internally by field decay, and resulting in multiple unstable configurations though without any large-scale magnetospheric twists, could result in sudden cracking and local rearrangements. This could be accompanied by bursts and profile changes, as well as with vortex line shifting. Why such surface motion does not produce significant magnetospheric twists is, however, puzzling, given that field lines are thought to be anchored in the crust; perhaps only for large motions do field lines become sufficiently twisted for enhanced X-ray emission to be produced.

Dib et al. (2008) showed that other AXP glitches have been unaccompanied by radiative changes. For example, AXP 1E 1841−045 has glitched multiple times yet its pulsed flux remains very steady. Such radiatively “silent” glitches may be a result of internal activity that does not result in significant twisting of outer magnetosphere field lines, where as radiatively “loud” glitches could be those for which the
magnetosphere is impacted. We note in fact that thus far the data are consistent with all AXP radiative outbursts being accompanied by timing anomalies. This may also be true of SGRs, though in those cases, timing anomalies are harder to establish because of the difficulty in achieving phase-coherent timing in quiescence.

5. SUMMARY AND CONCLUSIONS

We have reported on AXP 4U 0142+61 entering an active phase which was preceded with by a long-term increase in pulsed flux. The active phase, which commenced in 2006 March, consisted of a timing anomaly that can be described as a net “anti-glitch,” that is, a net spin-down following an initial spin-up that decayed on a timescale of 17 days. Following the glitch, we detected six bursts from the pulsar, the first ever observed from this source. Despite 10 yr of RXTE monitoring, the bursts all occurred in the narrow time span between 2006 April 6 and 2007 February 7. The sixth and largest burst had a unusual spectrum that cannot be described by any simple continuum model. Rather, it can be well fit if a broad spectral feature at 14 keV is included, as has been reported in other AXP bursts, as well as a narrow feature at 8 keV. The pulse profile of the source changed from double- to triple-peaked near the bursts, and underwent considerable evolution otherwise. At the burst epochs, the relative intensity of the three peaks significantly varied. The pulse profile is now relaxing to its pre-active phase morphology. Most aspects of 4U 0142+61’s emission changed during the active phase, with the notable exception of the pulsed flux (except near bursts). This argues against this event being associated with a sudden magnetospheric twist, as has been invoked for other AXP activity, and is suggestive of crustal evolution driven internally by the large magnetic field, though without significant magnetospheric twisting. We suggest that other, radiatively silent AXP glitches have a similar origin, whereas radiatively loud AXP timing events occur when the crustal motions cannot avoid significant twisting of the magnetic field lines.

We thank P. M. Woods and A. M. Beloborodov for useful discussions. This research has made use of data obtained through the High Energy Astrophysics Science Archive Research Center Online Service, provided by the NASA/Goddard Space Flight Center. This work has been supported by an NSERC Discovery Grant, the Canadian Institute for Advanced Research, and the Canada Research Chairs program, and by the Lorne Trotter Chair in Observational Astrophysics.
