ABSTRACT

Recently it has been observed that the scaling of jet power with black hole spin in galactic X-ray binaries is consistent with the predictions of the Blandford-Znajek (BZ) jet model. These observations motivate us to revisit the BZ model using general relativistic magnetohydrodynamic simulations of magnetized jets from accreting \((h/r \approx 0.3)\), spinning \((0 < a_* < 0.98)\) black holes. We have three main results. First, we quantify the discrepancies between the BZ jet power and our simulations: assuming maximum efficiency and uniform fields on the horizon leads to a \( \sim 10\% \) overestimate of jet power, while ignoring the accretion disk leads to a further \( \sim 50\% \) overestimate. Simply reducing the standard BZ jet power prediction by \( 60\% \) gives a good fit to our simulation data. Our second result is to show that the membrane formulation of the BZ model correctly describes the physics underlying simulated jets: torques, dissipation, and electromagnetic fields on the horizon. This provides intuitive yet rigorous pictures for the black hole energy extraction process. Third, we compute the effective resistance of the load region and show that the load and the black hole achieve near perfect impedance matching. Taken together, these results increase our confidence in the BZ model as the correct description of jets observed from astrophysical black holes.

Key words: black hole physics, gravitation, (magnetohydrodynamics) MHD, accretion, accretion discs

1 INTRODUCTION

The spins of ten stellar-mass black holes have been measured using the continuum fitting method (see McClintock et al. 2013 for a recent review of the details of the continuum fitting method and the uncertainties in the derived spin estimates). Seven of these black holes are so-called “transient” systems which have large amplitude outbursts. During outburst they reach close to the Eddington luminosity limit and near peak luminosity they eject blobs of plasma. The blobs move ballistically outward at relativistic speeds (Lorentz factor \( \gamma > 2 \)). Narayan & McClintock (2012) and Steiner et al. (2013) measured the peak radio luminosities of ballistic jet blobs, a proxy for jet power, from five transient systems. They find that the jet power is correlated with black hole spin, increasing by a factor of \( 1000 \) as the spin varies from \( 0.1 \) to \( 1 \). This suggests the blobs may be powered by black hole rotational energy.

The observed scaling of jet power with black hole spin is consistent with the predictions of the Blandford-Znajek (BZ) jet model (Blandford & Znajek 1977, MacDonald & Thorne 1982, Thorne et al. 1986). This model describes how magnetic fields drain a black hole of its rotational energy and drive powerful jets. It builds on earlier proposals for tapping black hole rotational energy using particles (Penrose 1969) and magnetic fields (Ruffini & Wilson 1973), and is a close cousin of the pulsar magnetosphere model of Goldreich & Julian (1969). The similarity between black hole and pulsar jets is particularly transparent in the membrane formulation of the BZ model (MacDonald & Thorne 1982, Thorne et al. 1986).

The BZ model has three free parameters: the angular velocity of the event horizon \( \Omega_H \), the angular velocity of magnetic field lines, \( \Omega_F \), and the magnetic flux threading the jet, \( \Phi \). Early attempts to determine \( \Omega_F \) (Lovelace et al. 1979; MacDonald & Thorne 1982, Phinney 1983) found (up to factors of order unity) \( \Omega_F/\Omega_H \approx 1/2 \). If one assumes \( \Omega_F/\Omega_H = 1/2 \), then the jet power predicted by the BZ model is \( \Omega_F/\Omega_H \approx 1/2 \) gives maximum jet efficiency. We refer to the BZ model with this assumption as the standard BZ model. Equation (1)

\[
p_{\text{BZ}} \approx \frac{1}{6\pi \Omega_f^2 \Phi^2}.
\]
is consistent with the jet power scaling observed from astrophysical black holes by Narayan & McClintock (2012) and Steiner et al. (2013).

There is now an extensive, decade-old literature on general relativistic magnetohydrodynamic (GRMHD) simulations of black hole jets, which further support and extend the BZ model. Komissarov (2003) presented the first time-dependent simulations of BZ jets and demonstrated that the model is stable. In these simulations, magnetic fields were imposed on the black hole at the outset.

Later simulations (including those in this paper), embed the black hole in a turbulent accretion disk, which then deposits magnetic fields onto the hole self-consistently. A funnel-shaped region develops along the black hole spin axis where the field geometry resembles a split monopole (Hirose et al. 2004). In this region, the flux of magnetic energy at the horizon is sometimes directed outward, away from the black hole McKinney & Gammie 2004; De Villiers et al. 2005. The distribution of electromagnetic fields and the angular momentum flux at the horizon are consistent with the BZ model (McKinney & Gammie 2004; McKinney et al. 2012). The flux of energy carried by gas is always directed into the black hole (Komissarov 2003). The strength of the jet is an increasing function of black hole spin (Krolik et al. 2003; McKinney 2005; Hawley & Krolik 2006) and the energy in the jet can be comparable to the energy in the accretion flow (Hawley & Krolik 2006). The magnetic field geometry is intermediate between the split-monopole and paraboloidal geometries considered by BZ (McKinney & Narayan 2007a,b). The strength of the simulated jet depends on the field geometry in the initial conditions, because this affects the final field strength of the black hole and disk (Beckwith et al. 2008; McKinney et al. 2012). The simulated scaling of jet power with black hole spin agrees with the BZ prediction (Tchekhovskoy et al. 2010, 2012). If the magnetic field is very strong, the jet can carry off more energy from the black hole than the accretion flow puts in (Tchekhovskoy et al. 2011). If the magnetic field is very weak, gas accretion can quench jet formation (McKinney et al. 2012). Prograde black holes drive more powerful jets than retrograde holes (Tchekhovskoy & McKinney 2012).

In this paper, we revisit our GRMHD simulations of jets from accreting, spinning black holes. We have three main results. First, we quantify the error introduced into the BZ jet power prediction by the standard approximations (maximum efficiency, uniform magnetic fields on the horizon, no disk thickness, and no gas accretion). Second, we check that the underlying physics generating simulated jets (torques, dissipation, and electromagnetic fields at the horizon) is correctly described by the membrane formulation of the BZ model. Third, we compute the effective resistance of the load region, where magnetic energy is converted into bulk gas motion. This analysis supports the prediction \( \Omega_{\text{crit}} / \Omega_{\text{H}} = 1/2 \) of simple load region models (Lovelace et al. 1979; MacDonald & Thorne 1983; Phinney, 1983).

The paper is organized as follows. In Section 2, we give an overview of the membrane formalism and our GRMHD simulations. In Section 3, we show that the simulated jet power is consistent with the BZ formula and quantify the main sources of discrepancy. In Section 4 and 5, we show that the torques, dissipation, and electromagnetic fields at the horizon in the GRMHD simulations are in excellent agreement with the BZ model. In Section 6, we discuss the conversion of magnetic energy into bulk gas motion in the load region and its relationship to \( \Omega_{\text{crit}} / \Omega_{\text{H}} \). We summarize our results in Appendix A. Appendix A re-derives the BZ jet power prediction. Appendix B gives 3D visualizations of the torques, dissipation, and electromagnetic fields on the black hole membranes of our GRMHD simulations.

2 PRELIMINARIES

2.1 The membrane formalism

MacDonald & Thorne (1983) recast the BZ model in the membrane formalism (see Thorne et al. 1986 for an overview). We will use this formulation for much of our analyses. It allows a local description of the conversion of gravitational energy into magnetic energy at the horizon. Another advantage is that it does not require any mathematics beyond three-dimensional vector algebra, so relations to non-relativistic mechanics are particularly transparent.

There are two pieces to the membrane formalism: we introduce fiducial observers (the ZAMOs), and we switch to a dual description of black holes that treats the horizon as a viscous membrane (but is mathematically equivalent to the usual description of black holes).

Understanding the flow of energy at the horizon presents a conceptual challenge: it is always possible to change the metric at a point to the flat, zero-energy Minkowski metric by a change of reference frame (equivalence principle), so there is no observer-independent way of defining the energy of the gravitational field at a point. The only way to give a local description of black hole energy extraction is to fix an observer. The fiducial choice in the Kerr metric is the zero angular momentum observer (ZAMO) Bardeen et al. 1973. Quantities measured at infinity do not depend on the choice of local observer. However, introducing the ZAMO is useful because it gives a concrete picture for the intermediate interactions between black hole and jet that result in black hole energy extraction. So we will often work in the ZAMO frame.

It is well-known that to an observer outside a black hole (such as a ZAMO), matter falling into the hole appears to freeze just outside as a result of gravitational redshift. This applies equally well to the matter which first formed the black hole. So the black hole’s energy, \( M \), and angular momentum, \( J \), appear spread out in a membrane covering the horizon. The “membrane paradigm” treats this membrane as a surrogate for the black hole. Every interaction of the external world with the black hole becomes concretely realized as an interaction with the membrane. It would be difficult to give a complete discussion of black hole energy extraction without the membrane formalism because we would not be able to say where the black hole energy is located to begin with. Of course, an observer falling into the black hole does not find the hole’s energy and angular momentum at the horizon (equivalence principle), but infalling observers are not relevant for astrophysics. The fact that different observers see the energy of the gravitational field in different places has been called “black hole complementarity” to highlight its similarity with wave-particle duality in quantum theory (Susskind et al. 1993).

2.2 GRMHD simulations

Our GRMHD simulations have been described in detail elsewhere Narayan et al. 2012; Penna et al. 2013; Sadowski et al. 2013, so we can be brief. We use the GRMHD code HARM (Gammie et al. 1996). A “quasi-local” energy, defined on surfaces rather than at points, can be defined in at least some cases. See Wang & Yiz 2005 for a recent approach and a summary of earlier work.

© 000 RAS, MNRAS 000, 000–000
There is no radiative cooling, so the disk becomes thick and hot. It evolves the metric (self-gravity is ignored). We consider four black hole spins: \( \frac{\sqrt{2}}{5} \). The notation is standard: \( \rho, u, p, a \) are the fluid rest mass density, internal energy, pressure, and four-velocity. The field \( b^\mu \) is the fluid frame magnetic field and \( h^\mu = g^\mu + u^\mu u_\nu \) is the projection tensor. The equation of state for the gas is \( p = \Sigma (\Gamma - 1)u \), where \( \Gamma = 5/3 \). There is no radiative cooling, so the disk becomes thick and hot. It is similar to an advection dominated accretion flow (Narayan & Yi 1994, 1995; Narayan et al. 2012).

The Kerr metric in Boyer-Lindquist \( (t, \phi, \theta, \phi) \) coordinates is:

\[
ds^2 = -(1 - 2Mr^2)/\Delta d\tau^2 - 4Mr^2 \Delta^{-1} \sin^2 \theta d\phi^2 + \Delta d\tau^2 + (r^2 + a^2 + 2Mr^2 \sin^2 \theta/r^2) \sin^2 \theta d\phi^2.
\]

We define the metric functions

\[
\Delta = r^2 - 2Mr + a^2,
\]

\[
p^2 = r^2 + a^2 \cos^2 \theta,
\]

\[
\Sigma^2 = (r^2 + a^2)^2 - a^4 \Delta \sin^2 \theta.
\]

Our notation follows Thorne et al. (1986). The simulations do not move the metric (self-gravity is ignored). We consider four black hole spins: \( a_\infty = a/M = 0, 0.7, 0.9, \) and 0.98.

HARM uses Kerr-Schild coordinates and Boyer-Lindquist coordinates. These coordinates have a couple of advantages over the membrane formulation for numerical computations. First, unlike the membrane formulation, they make Lorentz invariance manifest, so it is easier to impose energy and momentum conservation numerically. Second, computing in Kerr-Schild coordinates makes it trivial to impose boundary conditions at the inner edge of the numerical grid; the coordinates are horizon penetrating, so we simply place the inner boundary of the grid between the inner and outer black hole horizons and the black hole behaves as an event horizon. A major part of our work in this paper is converting the simulation results from Kerr-Schild and Boyer-Lindquist coordinates to the membrane formalism. It is only possible to give a local description of black hole energy extraction in the membrane formalism.

We use a logarithmically spaced radial grid and put the outer boundary of the grid at \( r \sim 10^5 M \); far enough away that nothing reaches it over the course of the simulation (so we do not need to worry about boundary conditions there). The \( \phi \) coordinate runs from 0 to \( \pi \) and the \( \theta \) coordinate runs from 0 to \( 2\pi \). The duration of the simulations varies from as short as \( t = 250,000 M \) to as long as \( t = 200,000 M \). The typical resolution is \( 256 \times 128 \times 64 \) in \( r, \theta, \phi \).

The Lorentz factor peaks near the edges of the jets rather than along the axes: there is a low Lorentz factor core. This is consistent with the BZ model. Magnetic torques extracting black hole rotational energy scale with the lever arm radius, \( \sigma \) (roughly the cylindrical distance from the black hole spin axis to the black hole membrane) as \( \tau = \sigma \times F \). Near the axes, \( \sigma \) (and so also torque) goes to zero, so the cores of the jets are less accelerated than the edges.

### 3.1 Jet Lorentz factor

The easiest way to detect jets in the simulations is to look at the gas Lorentz factor, \( \gamma \), in the \( x-y \) plane (where \( \gamma = r \cos \theta / \sqrt{1 - v^2} \)). This causes the fluid to become turbulent, leading to outward angular momentum transport and allowing fluid to accrete inwards and form an accretion disk. The accretion disk feeds the black hole and threads it with magnetic field lines. These magnetic fields tap the rotational energy of the black hole and drive jets. The remainder of this paper is an analysis of these jets.

### 3.2 Jet power vs. time

We introduce two proxies for jet power. The first is

\[
\rho^{\text{mag}} = \int_\Sigma \rho^{\text{mag}} dA, \quad (r = r_H),
\]

where \( dA = (r_H^2 + a^2) \sin \theta d\theta d\phi \) is an area element on the membrane and \( \alpha = r_H^2 \Sigma \sqrt{\Delta} \) is the lapse function. The outward normal vector is \( \nu = \sqrt{\Delta} / \rho \partial / \partial r \) and \( t \) is Boyer-Lindquist time. The integral is over the entire black hole horizon, \( H \), so it includes the jet and the accretion disk in the integral over \( \theta \).

The accretion disk might extract energy from the black hole via the Blandford-Znajek mechanism (Blandford & Znajek 1977). This causes the fluid to become turbulent, leading to outward angular momentum transport and allowing fluid to accrete inwards and form an accretion disk. The accretion disk feeds the black hole and threads it with magnetic field lines. These magnetic fields tap the rotational energy of the black hole and drive jets. The remainder of this paper is an analysis of these jets.
Table 1. GRMHD simulations

| Simulation | Initial field $a/M$ | $h/r$ | Resolution $(r, \theta, \phi)$ | Duration |
|------------|---------------------|-------|-------------------------------|----------|
| 1. SANE    | 0                   | 0.3   | $256 \times 128 \times 64$   | 200,000M |
| 2. SANE    | 0.7                 | 0.3   | $256 \times 128 \times 64$   | 100,000M |
| 3. SANE    | 0.9                 | 0.3   | $256 \times 128 \times 64$   | 50,000M  |
| 4. SANE    | 0.98                | 0.3   | $256 \times 128 \times 64$   | 25,000M  |
| 5. MAD     | 0                   | 0.3   | $264 \times 126 \times 60$   | 100,000M |
| 6. MAD     | 0.7                 | 0.3   | $264 \times 126 \times 60$   | 91,500M  |
| 7. MAD     | 0.9                 | 0.3   | $264 \times 126 \times 60$   | 44,000M  |

Figure 1. GRMHD simulation Lorentz factor and velocity streamlines for SANE runs. The spinning black holes power jets.

hole, but only the energy extracted into the jet is directly relevant for observations of black hole jets. (The jets observed by Narayan & McClintock (2012) and Steiner et al. (2013) are at $r \sim 10^{10}M$ so can be observationally distinguished from the accretion disk.) We thus introduce a second proxy for jet power:

$$\dot{P}_{\text{jet}} = \frac{dM}{dt} \left|_{A_{\text{jet}}} \right. = -\int_{A_{\text{jet}}} aT_{nt} dA, \quad (r = r_H).$$

(11)

Now we have restricted the integral to the jet region, $A_{\text{jet}}$, defined to be the region of the horizon where $-T_{nt} > 0$ (net energy leaving the hole). In other words, we do not include the accretion disk in
Simulations of Blandford-Znajek Jets

Figure 2. Same as Figure 1 but for MAD runs.

Figure 3. Jet power vs. time for our five GRMHD simulations with spinning black holes. \( P_{\text{mag}} \) (solid) and \( P_{\text{tot jet}} \) (dotted) are shown separately. The MAD runs (red) converge more quickly than the SANE runs (blue). The standard BZ prediction (solid black lines) is also shown.

The integral over \( \theta \). We have also switched from including only the magnetic energy flux, \( T_{\text{mag}} \), to including the combined magnetic and gas energy flux, \( T_{\text{nt}} \).

We expect \( P_{\text{mag}} \) to give the best fit to the BZ model, because the BZ prediction includes the entire horizon and considers only magnetic torques. We expect \( P_{\text{tot jet}} \) to be more relevant for jet observations.

Our simulations with non-spinning black holes always have \( -T_{\text{nt}} < 0 \) across the entire horizon, meaning the black hole never loses energy. So \( A_{\text{jet}} \) is empty and \( P_{\text{tot jet}} = 0 \), always.

The simulations with spinning black holes are more lively. We show \( P_{\text{mag}} \) and \( P_{\text{tot jet}} \) vs. time for these runs in Figure 3. Initially, none of the simulations have jets. The MAD simulations develop jets quickly, after just a few 1000\( M \), and soon thereafter the jet power saturates around a quasi-steady value. Remaining fluctuations in the jet power arise from turbulent fluctuations in the accretion disk feeding the black hole. The SANE simulations develop jets much more slowly. Even by the end of this set of runs the jet power has probably not converged to a quasi-steady value. The different onset time of jets in the SANE and MAD runs is easily understood. MAD runs begin with a single magnetic loop. This loop is so big that less than half of it is dragged onto the hole over the duration of the simulation. So the accretion flow is continually depositing magnetic flux of the same polarity on the horizon and a large mean field builds up. In the SANE runs the initial magnetic field is a series of small poloidal loops. The sign of the magnetic flux arriving on the hole is alternating with time and it is difficult for the hole to build up a large mean field. Nonetheless, at late times the SANE runs appear to be converging to what is perhaps the same quasi-steady jet power as the MAD runs.

It is interesting to compare \( P_{\text{mag}} \) (solid red and blue curves) and \( P_{\text{tot jet}} \) (dotted red and blue curves) in Figure 3. The former is always \( \sim 2-3 \) times larger than the latter. There are two reasons for this. First, \( P_{\text{tot jet}} \) does not include the accretion disk, so it is limited...
to a smaller region of the horizon. Second, even the jet regions, \(A_{\text{jet}}\), are not devoid of gas. In the polar regions of the flow, gas within a few gravitational radii of the horizon is falling onto the black hole. This gas torques the hole in the opposite sense as the magnetic fields, so the total jet power is lower than the magnetic black hole. This gas torques the hole in the opposite sense as

\[ \Phi = \frac{1}{6\pi} \Omega_\text{f}/\Omega_H (1 - \Omega_\text{f}/\Omega_H) \Omega_H^2 \Phi^2, \]

where \(\Omega_\text{f}\) is the field line angular velocity, \(\Omega_H\) is the horizon angular velocity, and \(\Phi\) is the magnetic flux threading the horizon. One obtains maximum efficiency for \(\Omega_\text{f}/\Omega_H = 1/2\). Switching from \(\Omega_\text{f}/\Omega_H = 1/2\) to \(\Omega_\text{f}/\Omega_H = 0.35\) lowers the jet power by 8%. In other words, assuming \(\Omega_\text{f}/\Omega_H = 1/2\) introduces an 8% error into the jet power estimate for our simulations. We conclude that \(\Omega_\text{f}/\Omega_H = 1/2\) is a good assumption for analytical applications of the BZ model.

The BZ jet power \(P\) also assumes uniform black hole spins, for which the magnetic field tends to bunch up near the polar axes (Tchekhovskoy et al. 2010). However, Figure 4 shows \(P^\text{BZ}\) and \(P^\text{mag}\) continue to agree to within 10% even at \(\alpha = 0.98\). We conclude that the assumptions \(\Omega_\text{f}/\Omega_H = 1/2\) and uniform \(B\) together create a \(\sim 10\% \) discrepancy between the BZ prediction \(\Omega_\text{f}/\Omega_H = 1/2\) and our simulations.

The jet power proxy \(P^\text{mag}\) measures the electromagnetic energy extracted across the entire black hole horizon. Not all of this energy is extracted into the jet; some of it is extracted into the accretion disk. We expect \(P_{\text{jet}}\) to be more relevant for jet observations than \(P^\text{mag}\) because the former is restricted to the jet region. Figure 4 shows \(P^\text{mag}\) (crosses) is about a factor of three lower than \(P^\text{mag}\) (filled circles). There are two reasons for this reduction. First, \(P^\text{mag}\) is restricted to a smaller region of the horizon, the jet region. Second, even within the jet region, there are gas torques counteracting the magnetic torques, further lowering \(P^\text{mag}\).

To isolate the relative importance of these two effects, we introduce a third proxy for jet power

\[ P^\text{jet} = -\int_{A_{\text{jet}}} a T_{\text{mag}}^\text{jet} \, dA, \quad (r = r_H), \]

which is intermediate between \(P^\text{mag}\) and \(P^\text{mag}\) (Figure 4 open circles). It is limited to the jet region, but it does not include gas torques. So the discrepancy between \(P^\text{mag}\) and \(P^\text{mag}\) measures the effect of restricting the jet power to the jet region. The discrepancy between \(P^\text{mag}\) and \(P^\text{mag}\) measures the importance of gas torques within the jet region. Figure 4 shows that these two effects are comparable: each contributes about 25% to the discrepancy between \(P^\text{mag}\) and \(P^\text{mag}\).

To summarize, the jet power proxy which is probably most relevant for jet observations, \(P^\text{mag}\), is roughly 60% lower than the BZ prediction \(\Omega_\text{f}/\Omega_H = 1/2\). Simply lowering \(P^\text{BZ}\) by 60% gives a good fit to our simulations. The main sources of discrepancy between the simulations and the BZ model are that the simulated jets do not cover the entire horizon and, within the jet region, there are gas torques partially counteracting the electromagnetic torques (Tchekhovskoy et al. 2010) have previously considered restricting the BZ model to a subregion of the full horizon and our power estimates are consistent with theirs. Our estimate for the importance of gas torques in the jet region should be considered an upper limit, as numerical floor activations in the polar regions introduce more gas than should otherwise be present. More work is needed to isolate the effect of the numerical floors and better determine the importance of gas torques in the jet region.

We have found that assuming \(\Omega_\text{f}/\Omega_H = 1/2\) and uni-
form horizon $B_0$ introduces order 10% discrepancies between the BZ jet power estimate and our simulations. It is worth noting that simulations of thicker ($h/r \sim 1$), more magnetized accretion flows have found $\Omega_\ell/\Omega_0 \approx 0.2$ (McKinney et al. 2013; Beskin & Zheltoukhov, 2013). Reducing $\Omega_\ell/\Omega_0$ from 0.5 to 0.2 lowers the jet power by 40% (equation (12)). This example serves to emphasize that details of the accretion flow can change jet power estimates by order unity factors. This suggests it will be difficult in practice to predict the power of astrophysical jets to better than a factor of order unity.

4 ENERGY EXTRACTION AT THE HORIZON

In the previous section, we found good agreement between the simulated and BZ jet power. In this section and the next, we turn to the underlying physics. We show that the torques and electromagnetic fields acting on the black hole membrane in our GRMHD simulations are in excellent agreement with the BZ model in its membrane formulation. All of the numbered equations in this section can be found in Thorne et al. (1986).

4.1 First law of black hole thermodynamics

The black hole membrane has mass $M$, angular momentum $J$, angular velocity $\Omega_0$, Bekenstein-Hawking temperature $T_H$, and Bekenstein-Hawking entropy $S_H$. These are related by the first law of black hole thermodynamics:

$$dM = \Omega_0 dJ + T_H dS_H.$$  \hspace{1cm} (14)

The left hand side is the total energy entering ($dM > 0$) or leaving ($dM < 0$) the membrane. It is related to jet power by $P_{jet} = -dM/dt$. The right hand side splits $dM$ into contributions from torques on the membrane, $\Omega_0 dJ$, and dissipation in the membrane $T_H dS_H$. It is impossible to extract energy from a nonspinning black hole because $\Omega_0 = 0$. The torque is negative when black hole rotational energy is being extracted and positive otherwise. The dissipation is always positive, as demanded by the second law of black hole thermodynamics.

In the BZ model, torques and dissipation have similar magnitudes. This might seem surprising: the Bekenstein-Hawking temperature $T_H \sim 1/h$ is minuscule. However, the Bekenstein Hawking entropy $S_H \sim 1/h$ is huge, so the product $T_H dS_H$ is finite and astrophysically relevant. The importance of the dissipation term is a key distinction between black holes and pulsars. Pulsars are perfect conductors, so $dM_{pulsar} = \Omega_{\text{pulsar}} dJ_{\text{pulsar}}$. Black holes are not perfect conductors, so jet power is a combination of torques and dissipation on the membrane. This explains why a pulsar magnetosphere has $\Omega_r = \Omega_{\text{pulsar}}$ while a black hole magnetosphere has $\Omega_r < \Omega_0$: pulsar field lines are frozen into the star, but black hole field lines slip with respect to the membrane because the latter is not a perfect conductor.

4.2 Torques and dissipation on the membrane

We have shown that GRMHD simulations of jets and the BZ model have the same $P_{pulsar}$. Now we will show they produce the same torques and dissipation on the membrane. Energy flow, torques, and dissipation on the membrane are related to the GRMHD stress energy tensor by:

$$\frac{dM}{dt} = -\int \alpha T_{\phi\phi} dA, \quad (r = r_H),$$  \hspace{1cm} (15)

$$\Omega_H \frac{dJ}{dt} = \Omega_H \int \alpha T_{\phi\phi} dA, \quad (r = r_H),$$  \hspace{1cm} (16)

$$T_H \frac{dS_H}{dt} = -\int \alpha^2 T_{\phi\phi} dA, \quad (r = r_H),$$  \hspace{1cm} (17)

where $i$ is the proper time of a ZAMO. The mathematical distinction between $dM/dt$ and $T_H dS_H/dt$ is that the former is related to the Boyer-Lindquist energy flux, $T_{\phi\phi}$, and the latter is related to the ZAMO energy flux, $T_H$. Boyer-Lindquist and ZAMO time are related at the membrane by

$$\hat{e}_i = \frac{1}{\alpha} \left( \hat{\alpha} \frac{\partial}{\partial t} + \Omega_H \hat{\alpha} \frac{\partial}{\partial \phi} \right).$$  \hspace{1cm} (18)

The first law of black hole thermodynamics is equivalent to equations (15)-(18), as an easy calculation shows:

$$T_H \frac{dS_H}{dt} = -\int \alpha^2 T_{\phi\phi} dA,$$  \hspace{1cm} (19)

$$= -\int \alpha T_{\phi\phi} dA - \Omega_H \int \alpha T_{\phi\phi} dA,$$  \hspace{1cm} (20)

$$= \frac{dM}{dt} - \Omega_H \frac{dJ}{dt}. \hspace{1cm} (21)$$

The second law of black hole thermodynamics, $T_H dS_H \geq 0$, is equivalent to the right hand side of equation (17) by the weak energy condition: $-T_{\phi\phi} \geq 0$ because ZAMOs are orthonormal observers.

The energy, flow, torques, and dissipation on the membrane in the GRMHD simulations are shown in Figures B1 (for the SANE runs) and Figure B2 (for the MAD runs). We have normalized each time-averaged quantity to the time-averaged accretion rate, $\dot{m}$. The membrane is depicted as a spherical surface with coordinates on the sphere corresponding to Boyer-Lindquist coordinates ($\theta, \phi$) in the usual way. The membrane is gaining energy at blue regions and losing energy at red regions.

The blue band near the equator is the accretion disk and the thickness of this band is set by the thickness of the disk. The accretion disk adds energy to the black hole. The yellow and red bands wrapping around the poles are the jet regions, $A_{jet}$, where the black hole is losing rotational energy. In the BZ model there is no accretion disk (so there would be no blue band) and the jet regions extend to the equator. In the GRMHD simulations the jet region is limited to areas outside the disk. The disk thickness in our simulations is $h/r \sim 0.3$ and this reduction in $A_{jet}$ lowers the jet power by a factor of 2–3. Physically this is not a particularly interesting distinction between GRMHD simulations and BZ jets, as it is easily absorbed into the BZ model by simply restricting the BZ jet power to $A_{jet}$.

The torques and dissipation on the membrane in the GRMHD simulations pass basic consistency checks. The torque on nonspinning black holes is zero everywhere. Dissipation is always positive as demanded by the second law of black hole thermodynamics (except possibly at the last couple grid cells near the poles where HARM has trouble with floors on magnetization). The net energy flux is always smaller than the torque because there is dissipation. Torques decrease near the poles as the lever arm radius $\sigma r$ goes to zero. This causes the dissipation and total energy flux to drop as well. Everything is amplified by black hole spin.

Figures B3 and B4 provide a more fine grained look at the membrane energy flux, torques, and dissipation in the GRMHD simulations.
Our simulations have shown that the hydrodynamic torques become negligible in the accretion disk region. The electromagnetic torques dominate in this region. An observer outside a black hole never sees a field line cross the horizon. The electric and magnetic fields measured by ZAMOs are three-dimensional vectors. The horizon behaves as a resistor with $R_H = 1$ (≈ 377 ohms in physical units) and the current is $J_H = E_H / R_H$. These are familiar expressions from ordinary three-dimensional mechanics for the electromagnetic torque on a membrane, $\sigma \times F_H$, and dissipation in a resistor, $R_H J_H^2$. This simplicity is an advantage of the membrane formalism.

5 ELECTROMAGNETIC FIELDS AT THE HORIZON

In the previous section, we showed that membrane torques and dissipation in the GRMHD simulations are related as the BZ model predicts: $\Omega_H dJ \approx -2T_H dS_H$. We also showed that extraction of black hole energy is a purely electromagnetic process mediated by electric and magnetic fields and currents acting on the black hole membrane. We now turn to the study of these fields and currents.

5.1 Membrane formalism

First, we review the necessary pieces of the membrane formalism (Thorne et al. 1986).

The electric and magnetic fields measured by ZAMOs are computed from the GRMHD Faraday tensor according to

$$ E = F^d, \quad B = F^{ad}, $$

where ZAMO time $\hat{t}$ is given by equation (18). These electric and magnetic fields are three-dimensional vectors.

At the black hole membrane, we split these electric and magnetic fields into their components perpendicular and parallel to the membrane. The perpendicular component of the magnetic field is $B^\parallel$, where the outward normal vector is related to $\partial/\partial r$ by $e_n = \sqrt{\gamma} / r (\partial/\partial r)$. The perpendicular component of the electric field is

$$ \sigma_H = E^\theta, \quad (r = r_H) $$

and called the membrane’s charge density, for the following reason. An observer outside a black hole never sees a field line cross the membrane, because gravitational redshifting causes everything falling in to appear to freeze just outside. Thus field lines appear to terminate on the membrane. As a result, ZAMOs infer a charge distribution on the membrane, $\sigma_H$, sourcing the radial electric fields. The inferred distribution of positive and negative charges on the membrane sums to $Q$, the charge of the black hole. Our simulations use the Kerr metric, so $Q = 0$ even when $\sigma_H$ is nonzero. For the same reason, an observer outside the black hole believes the parallel components of $\vec{E}$ and $\vec{B}$ are terminated at the membrane. To ZAMOs, the membrane is a conductor endowed with just the right fields to terminate $\vec{E}^\parallel$ and $\vec{B}^\parallel$. This defines the membrane fields:

$$ E_H^\parallel = a E^\parallel, \quad B_H^\parallel = a B^\parallel, \quad (r = r_H), $$

where $a = \rho / \Sigma \sqrt{\Lambda}$ is the lapse function. These electric and magnetic fields are two-dimensional vectors.

We have now packaged the six degrees of freedom of $F_{\mu\nu}$ into the set $B_\theta, \sigma_H, E_H^\parallel$, and $B_H^\parallel$. From this set, we can compute the horizon current, $J_H$. The horizon behaves as a resistor with $R_H = 1$ (≈ 377 ohms in physical units) and the current is

$$ J_H = E_H / R_H. $$

In these variables, the power generated by electromagnetic torques and dissipation on the horizon (16) are

$$ \Omega_H dJ / dt = \Omega_H \int \sigma [\sigma_H E^\theta + (J_H \times \hat{B}_H)^\parallel] dA, $$

$$ T_H dS_H / dt = \int R_H J_H^2 dA. $$

These are familiar expressions from ordinary three-dimensional mechanics for the electromagnetic torque on a membrane, $\sigma \times F_H$, and dissipation in a resistor, $R_H J_H^2$. This simplicity is an advantage of the membrane formalism.

5.2 Comparison of GRMHD and BZ electromagnetic fields

In (14) we showed that the BZ model and GRMHD simulations produce the same torques and dissipation on the membrane. We now show that the underlying electromagnetic fields are also the same. There are six degrees of freedom: $B_\theta, \sigma_H, E_H^\parallel$, and $B_H^\parallel$. The BZ model leaves $B_\theta$ a free parameter. The remaining degrees of freedom are predictions we can test against our GRMHD simulations. The $(t,\theta)$-averaged electromagnetic fields of our simulations are shown in Figures 15 (SANE runs) and 16 (MAD runs). The accretion rate varies from run to run, so we plot the fields in units of $\sqrt{\mu}$, where $\mu$ is the $(t,\theta,\phi)$-averaged accretion rate.

First consider the radial magnetic field, $B_\theta$. This is a free parameter of the BZ model. In our GRMHD simulations, it is spontaneously generated by the accretion disk. The relaxed field geometry has a simple structure. It is roughly uniform over the jet regions and the sign of the field is reversed in the northern and southern hemispheres. So it is similar to a split monopole, the simplest possible field.

Now consider the membrane electric field, $E_H^\parallel$. The BZ model assumes axisymmetry, which implies (Thorne & MacDonald 1982)

$$ E_H^\parallel = 0. $$

Our GRMHD simulations do not enforce axisymmetry, but the

2 Reasoning by analogy, $B_\theta$ is sometimes called the membrane’s magnetic monopole distribution.

© 0000 RAS, MNRAS 000, 000–000
time-averaged fields become roughly axisymmetric at the membrane. Figures B5 and B6 show $E_\hat{H}\approx 0$ and the membrane electric field runs north-south.

The standard BZ model fixes the $\hat{\theta}$-component of the electric field by winding up $B_n$: 

$$E_\hat{\theta} = -\frac{1}{2}v_H B_n, \quad \left(\Omega_F/\Omega_H = 1/2\right),$$

where $v_H = \pi\Omega_H$ is the velocity of the membrane (note $v_H = 1$ at the equator when $a_*= 1$). Figure 5 (middle panel) shows $-E_\hat{\theta}/(v_H B_n)$ as a function of $\theta$ for our GRMHD simulations. The simulations have $E_\hat{\theta} \approx -0.65v_H B_n$, so the simulated electric field is about 30% larger than predicted by the standard BZ model (equation [31]). This is because the simulations do not achieve perfect efficiency. For general $\Omega_F/\Omega_H$, the BZ model predicts [Thorne et al.]

Figure 5. Torques and electromagnetic fields at the membrane as a function of $\theta$. The line types are as follows. SANE runs: $a_*= 0.7$ (long dashed), $a_*= 0.9$ (dot-dashed), and $a_*= 0.98$ (dot-long dashed). MAD runs: $a_*= 0.7$ (dotted) and $a_*= 0.9$ (dashed). Solid lines indicate the standard BZ prediction. The simulation data should not be trusted near $\theta = 0$ and $\theta = \pi$, where low gas densities require numerical floor activations. The simulations differ from the standard BZ model near $\theta = \pi/2$ because the simulations have accretion disks and the BZ model does not. Over the remaining range of polar angles, the simulations and BZ model are in good agreement. The discrepancies that do appear can be traced to the field line angular velocity: the simulations have $\Omega_F/\Omega_H \approx 0.3$ and the standard BZ model assumes $\Omega_F/\Omega_H = 1/2$. 

© 0000 RAS, MNRAS 000, 000–000
As the current circulates through the magnetosphere, the magnetic energy extracted at the membrane is converted into bulk gas motion in the load region. The potential drop through the load region, \( V \), is related to \( V_H \) and \( V_L \) by energy conservation:

\[
V = V_H + V_L. \tag{37}
\]

The effective resistance of the load region is

\[
R_L = V_L/I. \tag{38}
\]

In the load region, the electric field is predominantly along \( \hat{z} \). So \( R_L \) peaks at turning points of the current, where \( \hat{J} \) is along \( \theta \). The integral curves of \( \hat{J} \) through the magnetosphere behave like wires attached to resistors, \( R_L \), at their turning points.

Numerically evaluating the line integral \( V_L = \int \vec{E} \cdot d\hat{S} \) for the loop \( \mathcal{L} \), highlighted in red in Figure 6, gives \( V_L \approx 0.9 \). Connecting the footpoints of this current loop across the membrane, we find \( V_H \approx 2 \).

\[
\frac{R_L}{R_H} = \frac{V_L}{V_H} \approx 0.45. \tag{41}
\]

Plugging \( R_L/R_H = 0.45 \) into equation (39) gives \( \Omega_f/\Omega_H = 0.31 \). The load resistance does not appear to depend strongly on the
Simulations of Blandford-Znajek Jets

Figure 7. Angular velocity of magnetic fields lines, \( \Omega_F/\Omega_H \), at the membrane of our \( a_*=0.7 \) MAD simulation.

Figure 8. \((t,\theta,\phi)\)-averaged field line angular velocity, \( \Omega_F/\Omega_H \), as a function of \( \Omega_H \) for SANE (blue) and MAD (red) simulations.

choice of current loop or black hole spin, but we save a detailed investigation for a future paper.

We can test this analysis by computing the field line angular velocity directly:

\[
\Omega_F = \frac{\alpha}{\sigma} \left( \dot{\varphi} - v_r \frac{B^\theta}{B^\phi} \right),
\]

(42)

where \( \dot{\varphi} \) is the gas velocity in the ZAMO frame. Figure 8 shows that the simulated \( \Omega_F/\Omega_H \) is roughly constant over the horizon (except near the poles, where numerical floor activations make the simulations unreliable).

For all five of our simulations with spinning black holes, the \((t,\theta,\phi)\)-averaged field line velocity is \( \Omega_F/\Omega_H \approx 0.35 \) (see Figure 8), close to the value estimated from \( R_L/R_H \). This supports the idea that the angular velocity of magnetic field lines is tied to the effective resistance of the load region, \( R_L/R_H \). Furthermore, the simulated load region and black hole achieve near perfect impedance matching, as anticipated (Lovelace et al. 1979; Phinney 1983).

More work is needed to understand how the simulated black hole and load achieve \( \Omega_F/\Omega_H \approx 0.3 \). MacDonald & Thorne (1982) have given an intuitive argument for nearly perfect impedance matching. The minimum velocity of particles sliding along magnetic field lines is (MacDonald & Thorne 1982)

\[
v_{\text{min}} = \frac{\Omega_F}{\Omega_H} \frac{1}{1 - \Omega_F/\Omega_H},
\]

(43)

If \( \Omega_F/\Omega_H \ll 1/2 \), then matter sliding along field lines has little inertia and the field tends to spin up. If \( \Omega_F/\Omega_H \gg 1/2 \), then matter is flung off of field lines and the resulting backreaction tends to spin down the field. This suggests the field is driven towards \( \Omega_F/\Omega_H \approx 1/2 \) in equilibrium. Perhaps this argument, or a variant thereof, underlies the simulated physics. We save a detailed study of this question for the future.

Figure 9 shows the gas and magnetic energy fluxes in the jet for the \( a_*=0.7 \) MAD simulation. The conversion of magnetic energy into gas energy is a gradual process and the load is a broad region, beginning a few gravitational radii from the black hole and continuing to \( r \sim 10,000 \). The gas energy flux first exceeds the magnetic energy flux around \( r \sim 300 \), at which point roughly half of the magnetic energy has been converted into gas energy. By \( r \sim 10,000 \) the energy in the jet is carried almost entirely by the gas.

The fact that the load region is concentrated far from the black hole, where frame dragging is unimportant, may go some way towards explaining why \( \Omega_F/\Omega_H \) is roughly independent of black hole spin (see Figure 8).

7 SUMMARY AND CONCLUSIONS

We have discussed GRMHD simulations of jets from accreting \((h/r \sim 0.3)\), spinning \((0 \leq a_\ast \leq 0.98)\) black holes, and their relationship with the BZ model in its membrane formulation. We showed that the simulated magnetic jet power, \( P_{\text{mag}} \), integrated
over the entire horizon, agrees with the standard BZ prediction \( \Omega_j/\Omega_H = 1/2 \) to within 10%. This is consistent with earlier simulations (Tchekhovskoy et al. 2010, 2012). We traced the order 10% discrepancies between the BZ model and our simulated \( P_{\text{mag}} \) to the standard BZ assumptions \( \Omega_j/\Omega_H = 1/2 \) and uniform \( B_u \).

The jet power proxy \( P_{\text{mag}} \) is integrated over the entire horizon, so it also includes power extracted into the accretion disk. We have separately considered the power extracted into the jet alone, \( P_{\text{jett}} \), and found this to be roughly 50% lower than \( P_{\text{mag}} \). This quantity is probably more relevant for jet observations. Simply lowering the standard BZ prediction \( \Omega_j/\Omega_H = 1/2 \) by 60% gives a good fit to the simulated \( P_{\text{jett}} \). For all spins, equation (A5) is approximately

\[
P_{\text{jet}} \approx \frac{1}{6\pi} \Omega_j^2 \Phi^2.
\]

This is the BZ model’s prediction for jet power. We compare it with the jet power of GRMHD simulations in §3.4.

**APPENDIX B: 3D VISUALIZATIONS OF GRMHD MEMBRANES**

On the following pages we give 3D visualizations of our GRMHD simulation data. We show the simulated torques, dissipation, and electromagnetic fields on the black hole membranes.

**ACKNOWLEDGMENTS**

We thank Jon McKinney and Sasha Tchekhovskoy for discussions. R.F.P was supported in part by a Pappalardo Fellowship in Physics at MIT. R.N. and A.S. were supported in part by NASA grant NNX11AE16G.

**APPENDIX A: BLANDFORD-ZNAJEK JET POWER**

In this Appendix, we derive the BZ jet power equation (1). The magnetic flux, \( d\Phi \), of a circular ribbon on the horizon between \( \theta \) and \( \theta + d\theta \) is (Blandford & Znajek 1977; Thorne et al. 1986)

\[
d\Phi = 2\pi B_u (r_H^2 + a^2) \sin \theta d\theta.
\]

The jet power from the ribbon is (Blandford & Znajek 1977; Thorne et al. 1986)

\[
dP_{\text{jet}} = 2\pi a \Omega_j^2 B_u^2 (r_H^2 + a^2)^3 \frac{\sin^3 \theta}{r_H^2 + a^2 \cos^2 \theta} d\theta,
\]

where

\[
\lambda = \frac{\Omega_j}{\Omega_H}(1 - \frac{\Omega_j}{\Omega_H})
\]

is the efficiency factor.
Figure B1. Energy flow (first column), torques (second column), and dissipation (third column) on the membrane for our GRMHD simulations with SANE initial conditions. Rows correspond to different simulations: $a_* = 0.98, 0.90, 0.70, 0.00$ (bottom to top). In all three columns, the membrane is losing energy at yellow-red regions (jets) and gaining energy at blue regions (accretion disk).
Figure B2. Same as Figure B1 but for MAD runs.
Figure B3. Same as Figure B1 except each term is split into its magnetic (left hemisphere) and hydrodynamic (right hemisphere) components.
Figure B4. Same as Figure B3 but for MAD runs.
Figure B5. Electromagnetic fields at the membrane for our GRMHD simulations with SANE initial conditions. Membrane $B_n$ (first column, left hemisphere), electric charge density (first column, right hemisphere), electric field (second column), and magnetic field (third column) are shown. On the membrane $\vec{J}_H = \vec{E}_H$, so the second column is also the membrane’s current density. The GRMHD simulation results shown here are correctly described by the BZ model.
