Abstract. The cell–cell adhesion molecule N-cadherin, with its associated catenins, is expressed by differentiating skeletal muscle and its precursors. Although N-cadherin’s role in later events of skeletal myogenesis such as adhesion during myoblast fusion is well established, less is known about its role in earlier events such as commitment and differentiation. Using an in vitro model system, we have determined that N-cadherin-mediated adhesion enhances skeletal muscle differentiation in three-dimensional cell aggregates. We transfected the cadherin-negative BHK fibroblastlike cell line with N-cadherin. Expression of exogenous N-cadherin upregulated endogenous β-catenin and induced strong cell–cell adhesion. When BHK cells were cultured as three-dimensional aggregates, N-cadherin enhanced withdrawal from the cell cycle and stimulated differentiation into skeletal muscle as measured by increased expression of sarcomeric myosin and the 12/101 antigen. In contrast, N-cadherin did not stimulate differentiation of BHK cells in monolayer cultures. The effect of N-cadherin was not unique since E-cadherin also increased the level of sarcomeric myosin in BHK aggregates. However, a nonfunctional mutant N-cadherin that increased the level of β-catenin failed to promote skeletal muscle differentiation suggesting an adhesion-competent cadherin is required. Our results suggest that cadherin-mediated cell–cell interactions during embryogenesis can dramatically influence skeletal myogenesis.

The association of similarly fated cells is a critical aspect of embryonic development. The cadherin family of proteins mediates cell–cell adhesion through homophilic interactions and thus promotes homogeneity within tissues (Takeichi, 1995). Their spatiotemporal pattern of expression during development suggests cadherins play an important role in the formation and maintenance of tissues (Takeichi, 1988). The best-characterized cadherins are classical cadherins including E-cadherin (uvomorulin), N-cadherin, and P-cadherin. Cadherins are calcium-dependent transmembrane proteins that interact intracellularly with a group of proteins known as catenins (Wheelock and Knudsen, 1991; Kemler, 1993; Gumbiner, 1996). The catenins link the cadherins to the actin cytoskeleton and are required for full adhesive activity of most cadherins (Nagafuchi and Takeichi, 1988, 1989; Ozawa et al., 1990; Knudsen et al., 1995; Rimm et al., 1995). β-catenin, which interacts with cadherins directly, has a role in signal transduction and the specification of cell fate (McCrea and Gumbiner, 1991; Ozawa and Kemler, 1992; Miller and Moon, 1996). Cadherin-mediated junctions serve as signaling centers and disruption of these junctions can lead to growth and developmental defects (Huber et al., 1996; Larue et al., 1996).

The formation of skeletal muscle is a developmental process that requires the commitment of mesodermal precursors, withdrawal from the cell cycle, and differentiation of myoblasts into terminally differentiated multinucleate myofibers (Olson, 1992). This process is controlled through a number of developmental checkpoints that regulate cell cycle arrest and the expression of skeletal muscle–specific genes (Ludolph and Konieczny, 1995). Skeletal muscle–specific transcription factors, including MyoD, control the program of tissue-specific transcription within the developing myoblasts and serve as early markers of skeletal myogenesis (Olson and Klein, 1994).

In one myogenic model system, the pluripotent P19 embryonal carcinoma cells can be induced to form skeletal muscle through the addition of DMSO or exogenous MyoD (Edwards et al., 1983). The induction of differentiation by either of these methods requires aggregation of cells in suspension (Edwards et al., 1983; Skerjanc et al., 1994). This requirement for close contact of similar cells during skeletal muscle myogenesis is known as the community effect. The community effect is important for the differentiation of somites, cell lines, and embryonic stem cells into skeletal muscle (Gurdon et al., 1993; Kato and Gurdon, 1993; Slager et al., 1993; Skerjanc et al., 1994;
Injection of mRNA encoding a dominant-negative cadherin into early *Xenopus laevis* embryos blocks the expression of MyoD in the early stages of skeletal muscle myogenesis (Holt et al., 1994). N-cadherin has been identified as a predominant cadherin in developing skeletal muscle and thus most studies have focused on its role in myogenesis. For example, function perturbing antibodies to N-cadherin inhibit skeletal muscle differentiation by primitive streak stage chick epiblast cells in vitro (George-Weinstein et al., 1997). Perturbation studies also demonstrated N-cadherin plays a role in myoblast interaction, the formation of myotubes, and in myofibrillogenesis (Knudsen et al., 1990; Mege et al., 1992; Peralta Soler and Knudsen, 1994). Recently, N-cadherin has been shown to play a role in the migration of skeletal muscle precursors to the limb bud (Brand-Saberi et al., 1996).

Our laboratory is interested in the role of cadherins in myogenesis and the potential role cadherins play in the specification of cell fate. In these studies we used the BHK cell line 2254-62.2. BHK cells exhibit myogenic potential through the expression of MyoD and low levels of sarcomeric myosin (Schaart et al., 1991; this study). However, they do not contain detectable cadherin. We introduced exogenous cadherin into this cell line to investigate the role of cadherins in myogenesis. Our results demonstrate that cadherins dramatically increase the expression of sarcomeric myosin and thus promote the differentiation of BHK cells into skeletal muscle. Differentiation in these cells is dependent on the formation of aggregates, or a community effect, with concomitant withdrawal from the cell cycle.

**Materials and Methods**

**Cells**
The BHK 2254-62.2 cell line was obtained from American Type Culture Collection (Rockville, MD) and grown in DME (Fisher Scientific, Pittsburgh, PA) with 7% FBS.

**Antibodies**
Myosin was detected with the mouse monoclonal anti-chicken pectoralis myosin antibody MF20 (Developmental Studies Hybridoma Bank; Bader et al., 1982). The 12/101 antibody is a skeletal muscle–specific mouse monoclonal antibody to newt skeletal muscle homogenate (Developmental Studies Hybridoma Bank, Johns Hopkins University, Baltimore, MD; Kintner and Brodeur, 1984). N-cadherin was detected with 6B3 (George-Weinstein et al., 1997) or 13A9 (Knudsen et al., 1995). β-catenin was detected with 15B8 (Johnson et al., 1993). E-cadherin was detected with the E9 rat monoclonal anti–E-cadherin antibody (Wheelock et al., 1987). Mouse monoclonal antibodies to E- and P-cadherin were purchased from Transduction Laboratories (Lexington, KY). A polyclonal pan-cadherin antibody was purchased from Sigma Chemical Co. (St. Louis, MO). Monoclonal anti–bromo-deoxyuridinyl (BrDU) was purchased from Amersham Corp. (Arlington Heights, IL). Polyclonal anti-MEF2 recognizing all isoforms was purchased from Santa Cruz Biotechnology (Santa Cruz, CA). The polyclonal anti-MyoD was a gift from A.J. Harris (University of Otago Medical School, Otago, New Zealand).

**Transfection of BHK Cells**
Transfection of the chicken N-cadherin cDNA was controlled by the human β-actin promoter in the expression vector pHβApr-Neo (pHβ-Ncad) (Murphy-Erdos et al., 1995) (gift of G. Grunwald, Thomas Jefferson University, Philadelphia, PA). A HindIII fragment containing the entire human E-cadherin cDNA was cloned into the HindIII site of pHβ Apr-1neo to create pHβ-Ecad (Lewis et al., 1997). A mutant cDNA encoding an N-cadherin missing 390 bp from the extracellular domain (Fujimori and Takeichi, 1992) was cloned into pHβApr-1neo to create pHβ-NcadΔ. BHK cells were cotransfected with 1.0 μg of cadherin DNA and 0.1 μg of pLkpac, which served as a more efficient selectable marker than the neo resistance gene within pHβApr-1neo. pLkpac was constructed by placing an AvaiI/SmaI fragment containing the puromycin resistance gene from pBSpacΔp in pLk-neo-1 (de la Luna et al., 1988; Hirt et al., 1992). Control cells were transfected with pLkpac alone. Transfections were carried out using Lipofectamine (GIBCO BRL, Gaithersburg, MD) according to the manufacturer’s instructions.

**Formation of Cell Aggregates**
Aggregates were formed by harvesting cells with trypsin/EDTA and suspending the cells at 1.5 × 10⁶ cells per ml in DME with FBS. 20-μl drops of media containing 3,000 cells per drop were pipetted onto the inner surface of the lid of a Petri plate. The lid was then placed on the Petri plate so that the drops were hanging from the lid with the cells suspended within them. To eliminate evaporation within the hanging drops, 5 ml of PBS was placed in the bottom of the Petri plate. For analysis, aggregates were harvested by pipette and dispersed for counting, extracted for Western blot analysis, or replated on slides for immunofluorescence microscopy.

**Cell Growth Assay**
A total of 1.5 × 10⁶ cells were plated in 20-μl drops containing 3,000 cells per drop and either suspended from Petri plate lids or placed as individual drops on tissue culture dishes. Cells were grown for 72 h and harvested with trypsin for cells on culture dishes or dispersed into single cells with trypsin for cells in hanging aggregates. Cells were counted microscopically using a hemocytometer and viability determined using Trypan blue exclusion.

**BrdU Labeling of Cells**
BHK cells were labeled with a 1:1,000 dilution of cell proliferation labeling reagent (Amersham Corp.) containing BrdU and fluoro-deoxyuridine for 2.5 h and fixed using paraformaldehyde. BrdU was detected with a monoclonal anti-BrdU antibody.

**Western Blot Analysis**
Cell monolayers were harvested by scraping, or suspended cell aggregates were collected by pipet. The cells were washed in PBS, and extracted in a 10-fold excess of 1× SDS sample buffer (50 mM Tris, pH 6.8, 20 mM DTT, 2% SDS, 0.1% bromophenol blue, 10% glycerol). Insoluble material was removed by centrifugation. An equal amount of protein from each sample was separated on SDS-polyacrylamide gels and electrophoretically transferred to nitrocellulose as described (Knudsen et al., 1995). Blots were blocked with 3% bovine serum albumin in Tris-buffered saline containing 0.05% Tween 20. Proteins of interest were detected with various primary monoclonal and polyclonal antibodies and the appropriate species-specific, alkaline phosphatase–conjugated secondary antibodies (Fisher Scientific). Blots were developed with nitro blue tetrazolium and 5-bromo-4-chloro-3-indoyl phosphate. Pretained molecular weight markers were purchased from Bio Rad Laboratories (Richmond, CA). High range molecular weight markers include myosin (205 kD), β-galactosidase (116.5 kD), bovine serum albumin (66 kD), ovalbumin (45 kD), and glyceraldehyde-3-phosphate dehydrogenase (32 kD), soybean trypsin inhibitor (24 kD), and lysozyme (16 kD). The presence of dye in the prestained standards causes some proteins to migrate at the indicated molecular weights rather than their true molecular weights.

**Immunofluorescence**
Cells were grown on glass slides for 2 d and fixed in methanol for 10 min at...
the levels of the exogenous cadherin resulted in a dramatic increase in the presence of calcium (not shown). Introduction of though it increased their ability to aggregate in suspension morphology of cells in monolayer cultures (Fig. 1 to sites of cell–cell adhesion but had little effect on the N-cadherin (Fig. 1). The exogenous N-cadherin localized with N-cadherin due to its established role in myogenesis. We initiated our studies with N-cadherin to examine the role of skeletal muscle development, and the myogenic potential of the BHK cells that lack detectable N-, E-, or P-cadherin (not shown). Moreover, β-catenin was found at low levels in the cytoplasm but was absent at the plasma membrane, suggesting the cells lack significant levels of transmembrane cadherin. In aggregation assays, the BHK cells exhibit a small degree of calcium-dependent cell–cell adhesion, which may result from a low level of an unidentified cadherin or from some other adhesion mechanism (Urssihara et al., 1977; data not shown). The BHK cells do express N-CAM and thus exhibit calcium-independent aggregation (not shown).

Given the significant role of cadherins in many aspects of skeletal muscle development, and the myogenic potential of the BHK cells that lack detectable cadherins, these cells presented a unique model system to examine the role of cadherins in differentiation. Thus, we transfected the BHK cells with exogenous cadherin and examined the effect of its expression on a biochemical marker of differentiation, i.e., sarcomeric myosin. We initiated our studies with N-cadherin due to its established role in myogenesis.

We transfected chicken N-cadherin into BHK cells and established several cell lines that express stable levels of N-cadherin (Fig. 1). The exogenous N-cadherin localized to sites of cell–cell adhesion but had little effect on the morphology of cells in monolayer cultures (Fig. 1 A), although it increased their ability to aggregate in suspension in the presence of calcium (not shown). Introduction of the exogenous cadherin resulted in a dramatic increase in the levels of β-catenin detected at cell–cell junctions by immunofluorescence light microscopy (Fig. 1 A) and in cell extracts by Western blot analysis (Fig. 1 B). This increase in catenin levels upon introduction of exogenous cadherin in cells lacking endogenous cadherin has been shown previously (Nagafuchi et al., 1991; Tanihara et al., 1994).

**N-cadherin Promotes Myogenesis Only in Aggregated BHK Cells**

Introduction of N-cadherin had no detectable effect on the overall level of sarcomeric myosin in BHK cells growing as a monolayer (Fig. 2 B), which at first glance suggested that N-cadherin does not promote differentiation. Differentiation of skeletal muscle cell lines can be triggered by removing FBS or other growth factors. A similar approach with monolayer cultures of BHK cells failed to induce differentiation, even when the cells expressed exogenous N-cadherin. However, other cells with myogenic potential, such as P19 teratocarcinoma cells or embryonic stem cells, are induced to differentiate into skeletal muscle through aggregation in suspension (Edwards et al., 1983; Slager et al., 1993). Aggregation likely mimics conditions in which tight cell–cell contacts form in vivo, such as within somites. To replicate these conditions, we brought the BHK cells into close contact by culturing them in hanging drops of DME containing 7% FBS, and examined the effect of this aggregation on their differentiation. Aggregation of cells containing exogenous N-cadherin resulted in the formation of large aggregates that did not disperse after replating the cells for 48 h (Fig. 3). In contrast, the suspended control cells lacking N-cadherin failed to form stable aggregates and readily dispersed upon replating (Fig. 3).

Aggregation of the N-cadherin–containing transfectants by suspension culture resulted in a dramatic increase in sarcomeric myosin heavy chain, a marker of muscle differentiation, whereas control cell aggregates showed no detectable change in myosin expression (Fig. 2). The increase in myosin expression in the N-cadherin transfectants was paralleled by an increase in the 12/101 antigen, a marker of skeletal muscle differentiation (Kintner and Brockes, 1984) (Fig. 2 A). To test the specificity of the N-cadherin–mediated induction of differentiation, we also aggregated the BHK cells with the lectins wheat germ ag-
glutinin and concanavalin A. Aggregation in the presence of either of these lectins did increase cell–cell adhesion but did not increase sarcomeric myosin levels, suggesting N-cadherin has a role in promoting differentiation beyond simple agglutination of the cells (not shown). The differentiation process observed in the N-cadherin–containing BHKs proceeded over a 72-h-period in suspension culture with a gradual increase in myosin expression (not shown). For each of the following experiments we examined differentiation in suspension cultures at the 72-h-time point.

**N-cadherin Alters the Growth of BHK Cells in Aggregates**

Differentiation into skeletal muscle requires coordinated withdrawal from the cell cycle and activation of myogenic transcription factors (Ludolph and Konieczny, 1995). Since N-cadherin was capable of promoting differentiation of BHKs in aggregates but not the monolayer cultures, we were interested in its potential to affect the growth rate of these cells in monolayer and suspension cultures.

Exogenous N-cadherin had no effect on the proliferation of BHK cells grown as monolayer cultures in the presence of serum (Fig. 4A). However, when BHK cells were cultured as aggregates in the presence of serum, their growth decreased significantly in comparison to the attached cells. Moreover, this inhibition was enhanced in cells expressing N-cadherin (Fig. 4A). There was no difference in the percentage of nonviable cells in any of the cultures. These results suggest that suspension culture induces withdrawal from the cell cycle and that this is further enhanced by N-cadherin. The inhibition of cell proliferation in control aggregates did not stimulate differentiation. However, the enhanced inhibition of growth induced by N-cadherin in the aggregates may play a role in promoting their differentiation into skeletal muscle.

Given the inhibition of growth induced by N-cadherin–mediated aggregation and the role of N-cadherin in the promotion of myogenesis, we wanted to determine whether the cells expressing myosin were postmitotic. Our experiments demonstrated that cells within the N-cadherin–expressing aggregates express myosin (Fig. 2), whereas the majority of those in a monolayer around the aggregate did not. We examined the mitotic state of the cells within these aggregates using BrdU labeling and found that BrdU was...
incorporated into many cells on the periphery of the aggregates, whereas the vast majority of cells within the aggregates failed to incorporate BrdU (Fig. 4 B). Double labeling using anti-myosin and anti-BrdU monoclonal antibodies and isotype-specific secondary antibodies revealed that myosin positive cells on the periphery of the aggregate did not incorporate BrdU. A total of 517 cells within 10 independent fields on the periphery of an aggregate were analyzed and 45% of the cells were positive for BrdU, 16% were positive for myosin, but none were positive for both myosin and BrdU. The lack of BrdU incorporation within the myosin positive aggregates provides further evidence that N-cadherin promotes differentiation and withdrawal from the cell cycle.

Two of the transcription factors that cooperate to activate skeletal muscle myogenesis, MyoD and MEF2, both respond to growth control signals during differentiation (Olson et al., 1991; Ludolph and Konieczny, 1995; Molkentin et al., 1996). Given our finding that N-cadherin inhibits proliferation and enhances sarcomeric myosin levels in aggregated BHK cells, we were interested in the possible effect N-cadherin-mediated aggregation may have on levels of MyoD and MEF2. Therefore, we examined the levels of MEF2 and MyoD in suspended aggregates using Western blot analysis. We found that suspension culture with concomitant withdrawal from the cell cycle slightly increased the levels of MEF2 and MyoD above those found in cells grown as a monolayer (Fig. 5). However, the presence of N-cadherin did not have any detectable effect on the levels of MyoD or MEF2 in either monolayer or suspension cultures (Fig. 5).

**E-cadherin Also Promotes the Differentiation of BHK Cells**

N-cadherin is expressed by skeletal muscle precursors and has been implicated in the differentiation of skeletal muscle (George-Weinstein et al., 1997). Other cadherins, such as E-cadherin, can induce strong cell–cell adhesion but are not found in skeletal muscle. Therefore, we sought to determine whether stimulation of myogenesis by N-cadherin in BHK cells was specific to N-cadherin or if another cadherin, even one not normally expressed by skeletal muscle, also could stimulate differentiation. Therefore, we transfected the BHK cells with human E-cadherin. Similar to those with N-cadherin, cells expressing E-cadherin showed increased cell–cell adhesion in an aggregation assay (not shown) and also had increased levels of β-catenin relative to control cells (Fig. 6). Moreover, cells containing E-cadherin showed differentiation properties similar to those with N-cadherin (i.e., upon aggregation in suspension culture, the cells expressed increased levels of sarcomeric myosin) (Fig. 6). These results demonstrate that cadherin-mediated stimulation of skeletal muscle differentiation is not N-cadherin specific, and likely can be accomplished by any cadherin expressed by skeletal muscle cells or their precursors.

**Nonfunctional N-cadherin Increases β-catenin but Does Not Promote Differentiation**

Enhanced differentiation of BHK cells into skeletal mus-
mediated adhesion and not simply elevated levels of monolayer cultures or aggregates, suggesting that cadherin into BHK cells failed to promote differentiation in either (Fig. 7). However, introduction of this mutant N-cadherin cDNA encoding mutant N-cadherin defective in cell–cell contact and therefore adhesion. The intracellular domain of this cadherin is internalized, and therefore β-catenin is due to increased levels of β-catenin. To test this possibility we transfected the BHK cells with a cDNA encoding mutant N-cadherin defective in cell–cell adhesion. The intracellular domain of this cadherin is intact and therefore β-catenin levels increase in its presence (Fig. 7). However, introduction of this mutant N-cadherin into BHK cells failed to promote differentiation in either monolayer cultures or aggregates, suggesting that cadherin-mediated adhesion and not simply elevated levels of β-catenin stimulates the differentiation of BHKs into skeletal muscle (Fig. 7).

Discussion

Skeletal muscle precursors contain multiple cadherins that together have an important role in establishing tissue homogeneity. M-cadherin is involved in myotube formation and the adhesion of satellite cells to mature muscle (Donalies et al., 1991; Zeschmkig et al., 1995). N-cadherin is involved in myoblast interaction and the formation of myotubes (Knudsen et al., 1990; Mege et al., 1992). Skeletal muscle precursors also contain cadherin-11 (Kimura et al., 1995), R-cadherin (Inuzuka et al., 1991), and T-cadherin (Ranscht, 1994). Although roles for N-cadherin and M-cadherin in later stages of myogenesis have been firmly established, less is known about the requirement of cadherins in the early stages of myogenesis. Holt et al. (1994) demonstrated that a dominant-negative cadherin mRNA, which perturbs the function of all cadherins, can inhibit early stages of myogenesis in Xenopus embryos. In addition, George-Weinstein et al. (1997) recently showed that function-per}-

Figure 6. E-cadherin promotes skeletal muscle myogenesis. Stable cell lines transfected with either pHβ-Ecad plus pLKpac (E-cadherin) or pLKpac alone (control) were aggregated and analyzed by immunofluorescence light microscopy as described in Fig. 2. Both E-cadherin and β-catenin localized to sites of cell–cell contact. E-cadherin was detected with E9, β-catenin was detected with 15B8, and myosin was detected with MF20. As with N-cadherin, increased myosin was observed only when the cells were aggregated in suspension.

Figure 7. Nonfunctional N-cadherin increases β-catenin but does not promote skeletal muscle differentiation. Stable cell lines transfected with either pHβ-NcadΔ plus pLKpac (truncated N-cadherin) or pLKpac alone (control) were aggregated and analyzed by immunofluorescence light microscopy as described in Fig. 2. Truncated N-cadherin was detected with 6B3, β-catenin with 15B8, and sarcomeric myosin with MF20. Cells expressing truncated N-cadherin and control cells spread as a monolayer after replating due to lack of strong cell–cell adhesion in either of these cultures.

cle does not appear to be N-cadherin specific. At this point, we wanted to distinguish between cadherin-mediated adhesion and the cadherin-mediated increase in β-catenin. Expression of any exogenous classical cadherin by these cells would be expected to increase both cell–cell adhesion and the level of endogenous β-catenin. Since β-catenin has been implicated in cell fate determination and intracellular signaling (Miller and Moon, 1996), it is possible that the stimulation of differentiation by endogenous cadherin is due to increased levels of β-catenin. To test this possibility we transfected the BHK cells with a cDNA encoding mutant N-cadherin defective in cell–cell adhesion. The intracellular domain of this cadherin is intact and therefore β-catenin levels increase in its presence (Fig. 7). However, introduction of this mutant N-cadherin into BHK cells failed to promote differentiation in either monolayer cultures or aggregates, suggesting that cadherin-mediated adhesion and not simply elevated levels of β-catenin stimulates the differentiation of BHKs into skeletal muscle (Fig. 7).

Discussion

Skeletal muscle precursors contain multiple cadherins that together have an important role in establishing tissue homogeneity. M-cadherin is involved in myotube formation and the adhesion of satellite cells to mature muscle (Donalies et al., 1991; Zeschmkig et al., 1995). N-cadherin is involved in myoblast interaction and the formation of myotubes (Knudsen et al., 1990; Mege et al., 1992). Skeletal muscle precursors also contain cadherin-11 (Kimura et al., 1995), R-cadherin (Inuzuka et al., 1991), and T-cadherin (Ranscht, 1994). Although roles for N-cadherin and M-cadherin in later stages of myogenesis have been firmly established, less is known about the requirement of cadherins in the early stages of myogenesis. Holt et al. (1994) demonstrated that a dominant-negative cadherin mRNA, which perturbs the function of all cadherins, can inhibit early stages of myogenesis in Xenopus embryos. In addition, George-Weinstein et al. (1997) recently showed that function-per-
Cadherins Promote Differentiation

Cadherins are responsible for the close association of groups of cells with a similar developmental fate. The associated cells then initiate and respond to further developmental signals. One possible result of this cadherin-mediated association is intracellular signaling via the cadherin–catenin complex. Several lines of evidence suggest β-catenin has an important role in development and signal transduction. β-Catenin shares homology with the Dro sophila segment polarity protein Armadillo, which also is found in cell junctions (Gumbiner, 1995; Peifer, 1995). Changes in β-catenin levels result in alterations of mesoderm formation in Xenopus and mouse (Heasman et al., 1994; Funayama et al., 1995; Haegel et al., 1995). In addition, signaling by Wnt leads to the accumulation of β-catenin in the cytoplasm and β-catenin can be translocated to the nucleus (Orsulic and Peifer, 1996; Papkoff et al., 1996; Schneider et al., 1996; Yost et al., 1996). Although the role of β-catenin in signal transduction makes it an attractive candidate for an enhancer of myogenesis, our studies suggest that the primary stimulatory effect of exogenous cadherins on myogenesis comes from the cadherin–catenin complex itself and cadherin-mediated adhesion. It is possible, however, that β-catenin stimulates myogenesis through a pathway that is dependent on functional cadherins.

The requirement of a close community of cells for differentiation has been demonstrated in several developmental systems, and cell–cell adhesion plays an important role in many of these systems (Gurdon et al., 1993). The formation of aggregates by primary thyroid cells alters cell–cell contacts and promotes their differentiation (Yap and Manley, 1993). The differentiation of trophoblast cells in culture also requires their aggregation and is associated with an increase in E-cadherin expression (Rebut-Bon neton et al., 1993). The importance of tissue morphology and the balance between cell–cell and cell–matrix adhesion in development was demonstrated recently in a tumorigenic breast cell line (Weaver et al., 1997). In this model system, nontumorigenic breast cancer cells cultured as three-dimensional aggregates differentiated and formed a basement membrane. In contrast, a spontaneous tumorigenic subline with known oncogenic mutations failed to undergo morphogenesis when grown as aggregates, and instead produced invasive colonies with poor cell–cell adhesion. The addition of integrin function perturbing antibodies to these tumorigenic aggregates promoted the formation of cell–cell junctions, withdrawal from the cell cycle, and differentiation. However, the same antibodies caused decreased cell–cell adhesion in the nontumorigenic cells and inhibited their differentiation. This study, like ours, illustrates the impact that tissue morphology and cellular interactions play in the regulation of cell growth and differentiation. Cellular condensation involving changes in cell shape and cell adhesion is a frequent occurrence in embryogenesis, i.e., somitogenesis. These changes are likely to alter many aspects of cell behavior, including proliferation and expression of transcription factors, all of which contribute to the control of cell and tissue differentiation both in vivo and in vitro.

In summary, our studies show that cadherin-mediated cell–cell adhesion, along with the presence of myogenic transcription factors (i.e., MyoD and MEF2) and withdrawal from the cell cycle, is necessary for skeletal muscle differentiation. Muscle differentiation is not stimulated by increased MyoD/MEF2 and decreased cell proliferation in the absence of cadherin-mediated cell–cell adhesion, even if the cells are brought into close contact. The signal(s) generated by the cadherin-mediated adhesion and the mechanism by which sarcomeric myosin levels are increased are subjects for future studies.

We thank L. Myers for expert technical assistance, M. Wheelock and A. Peralta Soler for critical reading of the manuscript, and M. George-Weinstein and K. Linask for helpful discussions. The MF20 and 12/101 antibodies were obtained from the Developmental Studies Hybridoma Bank maintained in the department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine (Baltimore, MD), and the Department of Biological Sciences, University of Iowa (Iowa City, IA) under contract N01-HD-2-3144 from the National Institute of Child Health and Human Development.

Received for publication 5 May 1997 and in revised form 16 July 1997.
