Abstract
Secondary spontaneous pneumothorax (SSP) is one of the major complications of pulmonary tuberculosis (TB), and it can be a life-threatening condition if it progresses to tension pneumothorax. A correct initial assessment and prompt intervention will prevent a hemodynamic deterioration in tension pneumothorax. Needle decompression followed by large-bore chest tube insertion is usually required in the management of SSP. We present a case of spontaneous TB-associated tension pneumothorax in a young adult which resolved with needle decompression without chest tube insertion.

Introduction
Secondary spontaneous pneumothorax (SSP) is one of the major complications of pulmonary tuberculosis (TB), and it can be a life-threatening condition if it progresses to tension pneumothorax [1]. The incidence of SSP in pulmonary TB was reported to be 1.3–5% [2]. Correct initial assessment and prompt intervention will prevent a hemodynamic deterioration in tension pneumothorax. The treatment approach usually includes immediate invasive management, including large-bore chest tube insertion and video-assisted thoracoscopic surgery.
However, in clinical settings with limited resources, this cannot be done promptly. In this report, we present a case of spontaneous TB-associated tension pneumothorax in a young adult which resolved with needle decompression without chest tube drainage (CTD) insertion.

Case Report

A 32-year-old male from a rural part of Kendal in Indonesia presented to our emergency department with shortness of breath with a history of pulmonary TB for 5 years, and he was a smoker. He had symptoms of chronic productive cough of more than 2 weeks’ duration along with significant weight loss, low-grade fever, and fatigue. The patient had a history of seeing multiple health facilities 3 months prior to his admission to our hospital. At least, he had visited 2 different hospitals and 1 public health center, and all of them had established a diagnosis of pulmonary TB. However, the patient showed low compliance with the treatment protocol and decided not to take the anti-tubercular medication for more than 2 months.

Our initial evaluation in the emergency department revealed slight tachycardia (heart rate 110 bpm), tachypnea (respiratory rate of 30×/min), blood pressure 100/80 mm Hg, and a sign of significant cyanosis. Pulse oximetry was 88% with room air, increasing to 95% on 100% oxygen 4 L/min via nasal cannula. Physical examination revealed significantly decreased breath sounds on the left hemithorax, shifting the heart sounds to the right hemithorax. Chest X-ray was obtained and showed collapse of the left lung with shifting of the heart and mediastinum to the opposite hemithorax and a prominent fibrotic lesion in the right hemithorax (Fig. 1). We used the Light index to estimate pneumothorax size [3]. On admission, chest X-ray showed prominent left-sided pneumothorax with a Light index of 85.8%. The patient was admitted to the level 0 infectious ward care for close monitoring with intravenous (IV) drip of aminophylline, ciprofloxacin IV 200 mg b.i.d., methylprednisolone IV 62.5 mg b.i.d., and 7–8 L/min 100% oxygen via a nonrebreathing mask, without any significant intervention. Laboratory tests were obtained: WBC was 25,870/mm$^3$ with neutrophils 89%, platelet count 611,000/mm$^3$, and smear-positive TB. Therefore, anti-tubercular treatment was started again according to the National TB Program [4].

Twenty-four hours after admission, the patient developed significant deterioration with cardiovascular compromise (blood pressure 129/89 mm Hg, heart rate 141 bpm, decreasing level of consciousness, SpO$_2$ 84%, cold extremities). Immediate needle decompression with an IV catheter of 14 G in the left hemithorax was conducted. However, the patient and family refused CTD insertion due to financial constraints. The physician decided to attach the IV catheter for 48 h after symptoms of the patient were relieved drastically. A second chest X-ray showed significant resolution of left lung collapse with Light index of 59.6% (Fig. 2). Subsequently, the patient was discharged home on TB treatment at day 3 with the next follow-up appointment as an outpatient 5 days after discharge.

Discussion/Conclusion

SSP is a pneumothorax that occurs in association with underlying lung disease, such as chronic obstructive pulmonary disease (COPD) and pulmonary TB. The incidence of SSP in pulmonary TB ranges between 1.3 and 5% [2]. SSP that does not receive prompt intervention may progress to tension pneumothorax, which is a life-threatening condition. Significant risk factors for the development of tension pneumothorax in pulmonary TB are co-infection,
advanced TB (i.e., fibrotic adhesion and the size of bullae), and smoking [5]. Our patient had several conditions that triggered tension pneumothorax rapidly, such as possibly coinfections as suggested by prominent leukocytosis and fibrotic adhesion in the right hemithorax, smoking, and the current treatment status (“default” status). In this case, ciprofloxacin IV and methylprednisolone IV were given due to possibly mixed infections as shown by laboratory results (significant leukocytosis and predominant segmented neutrophilia).

The pathogenesis of spontaneous tension pneumothorax in pulmonary TB includes necrosis of pleura and pleural-pulmonary fibrotic adhesion, which possibly allows air leakage to the pleural cavity and is termed pleural porosity [6]. The management of tension pneumothorax obviously requires immediate needle decompression followed by CTD insertion. In our case, the patient refused CTD insertion due to financial constraints. The physician decided to attach the IV catheter for 48 h. The patient had started to show significant clinical improvement immediately after needle decompression using a 14-G IV catheter with an anterior approach in the left hemithorax (Fig. 2). The drainage was not done on admission because the pulmonologist was not readily available for the chest tube thoracostomy backup procedure. Therefore, the pulmonologist only suggested a watchful observation in the infectious ward.

The use of a 14-G needle in emergency treatment in tension pneumothorax is supported by the Advanced Trauma Life Support guideline [7]. However, several studies did not support using a 14-G needle and suggested a longer needle with a minimum of 6.44 cm length [8–10]. In our case, needle decompression only, without further CTD insertion, showed 26.2% reduction in pneumothorax size.

Our case was unique since the patient had an advanced pulmonary TB with “doctor-shopping” habit, delayed significant intervention during admission, and refused the CTD insertion procedure.

Spontaneous TB-associated tension pneumothorax is a life-threatening condition and requires early recognition and prompt intervention to decrease the mortality burden.
