OBSERVATION OF THE HALO OF NGC 3077 NEAR THE “GARLAND” REGION USING THE HUBBLE SPACE TELESCOPE

SHOKO SAKAI AND BARRY F. MADORE

Received 2000 August 1; accepted 2001 March 7

ABSTRACT

We report the detection of upper main-sequence stars and red giant branch stars in the halo of an amorphous galaxy, NGC 3077. The observations were made using the Wide Field Planetary Camera 2 on board the Hubble Space Telescope. The red giant branch luminosity function in the I band shows a sudden discontinuity at \( I = 24.0 \pm 0.1 \) mag. Identifying this with the tip of the red giant branch (TRGB) and adopting the calibration provided by Lee, Freedman, & Madore and a foreground extinction of \( A_B = 0.21 \) mag, we obtain a distance modulus of \( (m - M)_b = 27.93 \pm 0.14_{\text{rand}} \pm 0.16_{\text{sys}} \). This value agrees well with the distance estimates of four other galaxies in the M81 Group. In addition to the RGB stars, we observe a concentration of upper main-sequence stars in the halo of NGC 3077, which coincides partially with a feature known as the “Garland.” Using Padua isochrones, these stars are estimated to be less than 150 Myr old. Assuming that the nearest encounter between NGC 3077 and M81 occurred 280 Myr ago, as has been predicted by the numerical simulations of Yun, the observed upper main-sequence stars are likely the result of star formation triggered by the M81 + NGC 3077 tidal interaction.

Subject headings: galaxies: distances and redshifts — galaxies: individual (NGC 3077) — galaxies: interactions — galaxies: stellar content

1. INTRODUCTION

Located in a small group of galaxies around M81, NGC 3077 is a low-luminosity peculiar galaxy classified as Irr II (Sandage 1961) or 10 pc (de Vaucouleurs, de Vaucouleurs, & Corwin 1976). It was once suggested that this galaxy was a Seyfert galaxy (Wiszniowski & Kleinmann 1968), but Demoulin (1969) later noted that its emission lines were too narrow to put it in the Seyfert class. NGC 3077 is characterized by its dusty appearance (Sandage 1961; Barbieri, Bertola, & di Tullio 1974, hereafter BBdT74), its many compact blue knots (BBdT74), and its very high \( M_V/L_B \) for typical S0 or I0 galaxies. Its metallicity is also higher by about a factor of 2 than expected for a small galaxy (Heckman 1980). Based on the spectral distribution covering 1000–9000 \( \AA \), Benacchio & Galletta (1981) concluded that NGC 3077 is composed of “a number of very hot young stars embedded in a smoother, cooler component.” This degree of recent star formation is confirmed by Hubble Space Telescope (HST) NICMOS observations made in the Paschen line by Böker et al. (1999).

Given its peculiar nature, NGC 3077 has been the focus of numerous studies emphasizing its significance with respect to galaxy interactions and the formation of dwarf galaxies. One of the more important “breakthrough” discoveries that greatly affected our understanding of the evolution of NGC 3077 was the detection of an H I bridge between M81 and this galaxy (van der Hulst 1979). More recent H I observations using the Very Large Array revealed the distribution of the gas at higher resolution, extending not only from M81 to NGC 3077 but also out to M82 (Yun, Ho, & Lo 1994). Using these results, Yun et al. (1994) were able to produce a numerical simulation of the dynamical evolutionary history of the M81 + M82 + NGC 3077 system. Although there had been several such simulations prior to Yun et al. (Cottrell 1977; van der Hulst 1977; Killian 1978; Brouillet et al. 1991), they were not as accurate; the fundamental difference between Yun et al. (1994) and earlier studies was that the former were able to include an H I disk surrounding NGC 3077.

At the periphery of NGC 3077, there is also a prominent stellar complex, nicknamed the “Garland” by Karachentsev, Karachentseva, & Borngen (1985, hereafter KK88). The precise origin of this feature is uncertain, although it is plausibly associated with the tidal interaction of NGC 3077 with M81 (KK88). Some, however, suggest that this stellar complex is actually a progenitor of a dwarf galaxy (KK88). At an assumed distance modulus of \( \sim 27.6 \) mag, the brightest stars at \( B \sim 21 \) mag in the Garland were thought to be blue supergiants (KK88).

As part of a long-term project to obtain distances to all the galaxies in the local volume within \( \sim 5 \) Mpc using the tip of the red giant branch (TRGB) method, we have made \( V \) and \( I \) observations of two regions in the halo of NGC 3077 using the Wide Field Planetary Camera 2 (WFPC2) on board the HST. The TRGB method has been proved to be an excellent distance indicator (da Costa & Armandroff 1990; Lee et al. 1993; Sakai 1999), especially for obtaining consistent distances to all morphological types of galaxies, including our case, in which we are building a complete volume-limited sample. The NGC 3077 halo regions observed with HST were chosen to overlap with part of the Garland stellar concentration. In this paper, in addition to reporting the detection of the red giant branch stars in NGC 3077, we report observations of resolved

upper main-sequence stars in the Garland. The observations and data reduction procedures are briefly described in § 2. We then discuss the detection of the RGB stars and the determination of a distance to NGC 3077 measured by the TRGB method in § 3, followed by a discussion of the upper main-sequence stars observed in our frames in § 4.

2. OBSERVATIONS

Two positions in the halo region of NGC 3077 were chosen for our HST observations. A digital sky survey image of NGC 3077 is shown in Figure 1, on which the HST/WFPC2 footprints are superimposed, indicating the two regions (Fields I and II) observed. They are located, respectively, ≈3′ southwest and ≈5′ south from the nucleus of the galaxy. The Planetary Camera (PC) chip, which covers the smallest area, is referred to here as Chip 1. The three Wide Field (WF) chips cover the three larger fields and are referred to as Chips 2, 3, and 4, respectively, numbered counterclockwise from the PC. A close-up HST image of one of the chips, WF2 field of Field I, is shown in Figure 2, illustrating the high degree of resolution into stars.

Fields I and II were observed on 1999 January 27 and 1998 October 23, respectively. Two exposures (400 s for Field I and 500 s for Field II) were taken using two filters (F555W and F814W) at each position. Cosmic rays on each image were cleaned before being combined to make a set of F555W and F814W frames.

The subsequent photometric analysis was done using point-spread function (PSF) fitting packages DAOPHOT and ALLSTAR. These programs use automatic star-finding algorithms and then measure stellar magnitudes by fitting a PSF that is constructed from other uncrowded HST images (Stetson 1994). We checked for a possible variation in the luminosity function as a function of the position on each chip by examining the luminosity functions for different parts of the chip. For each frame, we find identical luminosity functions, confirming that there are no significant systematic offsets originating from the adopted PSFs.

The F555W and F814W instrumental magnitudes were converted to the calibrated Landolt (1992) system as follows (a detailed discussion is found in Hill et al. 1998). The instrumental magnitudes were first transformed to the
Holtzman et al. (1995) 0".5 aperture magnitudes by determining the aperture correction that needed to be applied to the PSF magnitudes. This was done by selecting 20–30 brighter, isolated stars on each frame. Then all the stars were subtracted from the original image except for these selected stars. The aperture photometry was carried out for these bright stars at 12 different radii ranging from 0".15 to 0".5. The 0".5 aperture magnitudes were determined by applying the growth-curve analysis provided by DAOGROW (Stetson 1990), which were then compared with the corresponding PSF magnitudes to estimate the aperture corrections for each chip and filter combination. We use a different set of aperture corrections for the two fields. Most of the values agree with each other within 2 \sigma; however, slight offsets between the corrections in the two fields are most likely due to the fact that the PSFs do not sample the images in precisely the same way. When images are co-added, the combined images are not exactly identical to the original uncombined images; that is, the precise positions of stars on the frames are slightly different. Thus we should expect some differences in the aperture corrections of the same chip in two fields.

Finally, the 0".5 aperture magnitudes were converted to the standard system via the equation

\[ M = m + 2.5 \log t + C_1 + C_2 \times (V - I) + C_3 \\
\times (V - I)^2 + \text{a.c.}, \]

where \( t \) is the exposure time; \( C_1, C_2, \) and \( C_3 \) are constants; and a.c. is the aperture correction. \( C_1 \) is composed of several terms: (1) the long-exposure WFPC2 magnitude zero points, (2) the DAOPHOT/ALLSTAR magnitude zero point, (3) a correction for multiplying the original image by 4 before converting it to integers (in order to save the disk space), (4) a gain-ratio term because of the difference between the gain settings used for NGC 3077 and for the Holtzman et al. (1995) data (7 and 14, respectively), (5) a correction for the pixel area map, which was normalized differently from that of Holtzman et al. (1995), and (6) an offset between long and short exposure times in the \( HST \) zero-point calibration. \( C_2 \) and \( C_3 \) are color terms and are the same for all four chips.

In Table 1, we list the \( V \) and \( I \) magnitudes of selected bright reference stars in NGC 3077. The columns list the
following: (1) WFPC2 image root name; (2) chip number; (3) and (4) the \((x, y)\) coordinates of the stars, respectively; (5) and (6) right ascension and declination (J2000), respectively; (7) and (8) \(V\) magnitude and errors; and (9) and (10) \(I\) magnitude and errors.

### 3. DETECTION OF THE RED GIANT BRANCH STARS AND THE DISTANCE TO NGC 3077

In Figure 3, \((V - I) - I\) color-magnitude diagrams (CMDs) for stars in both observed halo fields of NGC 3077 are shown. Because the exposure time was slightly shorter for the observations of Field I, the incompleteness magnitude is brighter for this field. The CMDs can be characterized by their prominent red giant branches \([\sim (V - I) \sim 2\; \text{mag}]\) and by the upper main-sequence \([\text{blue plume at } (V - I) \sim 0.0\; \text{mag}]\) stars, which are especially evident in Field II. We will return to the discussion of the main-sequence stars in §4.

The top panels of Figure 4 show \(I\)-band luminosity histograms for all stars in Fields I and II, whereas the bottom panels show those restricted to the red giant stars, defined as having colors between \(1.0 < (V - I) < 3.5\; \text{mag}\). The color restriction eliminates obvious main-sequence stars and limits the sample of RGB stars. The comparison of upper and lower histograms again suggests that the Field II stellar population is composed of a larger fraction of non-RGB stars.

There is a jump, especially in Field II, in the luminosity function at \(I \approx 24.0\; \text{mag}\). We identify this feature with the TRGB. The TRGB marks the onset of a core helium flash in old, low-mass stars. These stars evolve up the red giant branch but suddenly change their physical characteristics upon the ignition of helium in their cores. The magnitude at which this transformation takes place turns out to be extremely insensitive to both metallicity and age (Iben & Renzini 1983) in the \(I\) band \((\sim 8200\; \text{Å})\), manifesting itself as an abrupt discontinuity in the luminosity function at \(M_I \approx -4\; \text{mag}\). The insensitivity of the TRGB magnitude in the \(I\) band has been confirmed both observationally and theoretically (da Costa & Armandroff 1990; Lee et al. 1993; Salaris & Cassisi 1997). The empirical calibration (Lee et al. 1993) used consistently in this series is derived from the
distances to four Galactic globular clusters measured using the RR Lyrae distance scale, based on the theoretical horizontal branch model for $Y_{05} = 0.23$ of Lee, Demarque, & Zinn (1990), which corresponds to $M_{V, RRLyrae} = 0.57$ mag at $[\text{Fe/H}] = -1.5$. The globular clusters used in the calibration span the metallicity range of $-2.2 < [\text{Fe/H}] < -0.7$ dex.

To measure the distance to NGC 3077 using the TRGB
method, we select the stars in WF Chips 2 and 4 of Field I. This is because (1) Field I is less contaminated by upper main-sequence stars, and (2) WFC2 and 4 are centered on less crowded regions. The Gaussian-smoothed $I$-band luminosity function is shown in the top panel of Figure 5. A jump in the number count is clearly detected at $I \sim 24.0$ mag. We apply an edge-detection filter, which is a modified version of a Sobel kernel ($-1, 0, +1$), to the luminosity function to objectively determine the position of the TRGB following $E(m) = \Phi(m_n + \sigma_m) - \Phi(m_o + \sigma_m)$, where $\Phi(m)$ is the number of stars per unit magnitude integral at magnitude $m$, and $\sigma_m$ is the typical photometric error of stars at magnitude $m$. For the details of the Sobel filter application, readers are referred to the Appendix of Sakai, Madore, & Freedman (1996). The results of the convolution are shown in the bottom panels of Figure 5. The position of the TRGB is identified with the highest peak in the filter output function. For NGC 3077, we obtain $I_{TRGB} = 24.0 \pm 0.1$ mag.

We use the empirical calibration given by Lee et al. (1993) to determine the distance to NGC 3077, which is expressed as $(m - M)_I = I_{TRGB} - M_{bol} + BC_I$. The bolometric magnitude, $M_{bol}$, and the bolometric correction, $BC_I$, are given in terms of the metallicity of the RGB stars: $M_{bol} = -0.19[\text{Fe/H}] - 3.81$ mag, and $BC_I = 0.881 - 0.243 (V - I)_{TRGB}$. The metallicity [Fe/H] is expressed as a function of the $(V - I)$ color: $[\text{Fe/H}] = -12.65 + 12.6(V - I)_{-3.5} - 3.3(V - I)^2_{-3.5}$, where $(V - I)_{-3.5}$ is measured at the absolute $I$ magnitude of $-3.5$ mag. For the halo stellar population in NGC 3077, we observe $(V - I)_{TRGB} = 2.25 \pm 0.6$ mag and $(V - I)_{-3.5} = 2.0 \pm 0.5$ mag. Substituting these values into the above equations, we obtain $BC_I = 4.02 \pm 0.07$ mag, thus yielding $(m - M)_I = 28.02 \pm 0.14$ mag. The foreground extinction in the direction of NGC 3077 is $A_B = 0.21$ mag (Burstein & Heiles 1982). Using conversions of $A_V = E(V - I) = 2.45$ and $R_V = A_V/E(B - V) = 3.2$ (Dean, Warren, & Cousins 1978; Cardelli, Clayton, & Mathis 1989), we obtain $A_V = 0.09$ mag. Thus, the dereddened distance modulus of NGC 3077 is $(m - M)_0 = 27.93 \pm 0.12$, with a $0.07$ mag uncertainty in the edge detection as well as the $0.07$ mag uncertainty in the TRGB absolute calibration, which is due to the color spread of the RGB stars. The two uncertainties are added in quadrature to yield the random error of $0.12$ mag. The systematic uncertainties, on the other hand, come mainly from the TRGB calibration ($\pm 0.15$ mag) and the $HST$ photometry zero point ($\pm 0.05$ mag). The details of the nature of the systematic uncertainty have been discussed previously in Sakai & Madore (1999).

The distance to NGC 3077 we obtain in this paper compares very well with other distance estimates to galaxies in the M81 group. In Table 2 we tabulate five galaxies whose distances have been estimated using either the TRGB method or Cepheid variable stars. Remarkably, all five distances agree within $1\sigma$ of each other. In the plane of the sky, the five galaxies have a projected transverse separation of approximately 120 kpc. Along the line of sight, the depth of the M81 group formally extends for $\sim 350$ kpc, but the uncertainty on the line-of-sight thickness is itself about $\pm 250$ kpc. It is plausible that these five galaxies are all contained within a sphere of radius 60 kpc.

4. DETECTION OF UPPER MAIN-SEQUENCE STARS IN THE HALO: TIDALLY INDUCED STAR FORMATION?

In Figure 3, we present $I(V - I)$ CMDs for the two fields in the halo of NGC 3077, observed using $HST$. Field II is positioned farther away from the main body of the galaxy than Field I. However, we also noted that there are a significant number of upper main-sequence stars in Field II.

**Fig. 5.** _Top:_ Gaussian-smoothed $I$-band luminosity function. A jump in the number count is clearly observed at $I \sim 24.0$ mag. _Bottom:_ Output of an edge-detection filter applied to the luminosity function. The position of the TRGB is indicated by the highest peak in the output function.

**Table 2**

| Galaxy   | R.A. (J2000) | Decl. (J2000) | Distance Modulus (mag) | Method   | Reference          |
|----------|--------------|---------------|------------------------|----------|--------------------|
| M81      | 09 55 33.2   | +69 03 55     | 27.8 ± 0.2             | Cepheids | Freedman et al. (1994) |
| M82      | 09 55 52.2   | +69 40 48     | 27.95 ± 0.14           | TRGB     | Sakai & Madore (1999) |
| NGC 3077 | 10 03 19.2   | +68 43 59     | 27.93 ± 0.14           | TRGB     | This paper          |
| BK5N     | 10 04 41.1   | +68 15 22     | 27.9 ± 0.15            | TRGB     | Caldwell et al. (1998) |
| F8D1     | 09 44 47.1   | +67 26 19     | 28.0 ± 0.10            | TRGB     | Caldwell et al. (1998) |

**Note:** Units of right ascension are hours, minutes, and seconds, and units of declination are degrees, arcminutes, and arcseconds.
Figure 6.—Distribution in the plane of the sky of all stars found using the DAOPHOT package. Also overplotted by solid circles are the upper main-sequence stars which are defined on the CMD as those satisfying $I \leq 26.0$ mag and $-0.4 \leq (V - I) \leq 0.7$ mag. The cross represents the position of the nucleus of NGC 3077, which is at R.A. = $10^h 03^m 20^s.3$ and decl. = $68^d 44^m 02^s$.

Figure 6, we show the distribution in the plane of the sky of all stars found using the DAOPHOT package. Also overplotted by solid circles are the upper main-sequence stars which are defined on the CMD as those satisfying $I \leq 26.0$ mag and $-0.4 \leq (V - I) \leq 0.7$. Two features can be observed here: (1) a concentration of blue stars is found around R.A. ($J2000 = 10^h 03^m 10^s$ and decl.$(J2000) = 68^d 42^m 30^s$, which coincides with the outer region of the main body of the galaxy; (2) a concentration of blue stars is found in the WF Chips 2 and 3 of Field II. The distribution of the RGB stars follows what is expected for the halos of galaxies, with its surface brightness decreasing as a function of radial distance from the center of the galaxy. However, the upper main-sequence stars are distributed in a distinctly different fashion, characterized by concentrations that are separated from the main body of NGC 3077. The region around R.A. = $10^h 03^m 35^s$ and decl. = $68^d 40^m 00^s$ overlaps with the edge of a stellar concentration nicknamed the “Garland.” As mentioned in § 1, the causal origin of this feature is uncertain, even though it is very likely associated with the previous tidal interaction of galaxies in the M81 group.

Although a careful analysis of the star formation history of young stars in this region would require a better set of data, preferably with wider spatial coverage and deeper photometry, in this section we examine the properties of these upper main-sequence stars in the Garland region.

We begin by comparing our observed CMD with the Padua theoretical isochrones (Bertelli et al. 1994). Unfortunately, there is no published measurement of the abundance of NGC 3077. However, Martin (1997) reports that the Population I metallicity of this galaxy is likely larger than $\frac{1}{2} Z_\odot$. In her spectroscopic survey of nearby dwarf galaxies, she detected no [O III] $\lambda$4363 line in NGC 3077. Based on the strength of [N II] $\lambda$6584, she suggests that the abundance of NGC 3077 is at least $\frac{1}{2} Z_\odot$ and possibly much larger. This Population I abundance is consistent with the Population II abundance in the sense that the former is slightly larger than the latter estimated above using the colors of the red giant branch stars ([Fe/H] $\leq -0.6$, which corresponds to $Z = 0.005$). However, we note here that the Population II metallicity inferred by the RGB stars is rather high for a small dwarf galaxy such as NGC 3077. The reddest RGB stars are comparable to those of, e.g., 47 Tuc, a Galactic globular cluster with a metallicity of [Fe/H] $\sim -0.7$. This value is extremely high if NGC 3077 were to follow the luminosity-metallicity relation for dwarf galaxies. We will address this point later in
The Padua isochrone library provides the stellar evolution tracks for $Z = 0.004$ and $Z = 0.008$. We plot a set of isochrones for both of these abundances in Figure 7. The number corresponding to each isochrone is the logarithm of age. The main-sequence stars span the ages from $\sim 30$ up to $\sim 125$ Myr.

Another way of presenting the star formation timescale is the $V$-band luminosity function of upper main-sequence stars, which is shown in Figure 8. The main-sequence turnoff (MSTO) ages are indicated as well on this plot. A simple artificial star test suggests that our $V$-band photometry is complete down to $V \approx 25.5$ mag, which is consistent with the luminosity function turnover at 25.5–26.0 mag. Again, these main-sequence stars up to $V \approx 25.5$ mag correspond to those of MSTO aged up to $\sim 150$ Myr.

The Garland, where the upper main-sequence stars are found, was first noticed by BBdT74 and was later described by Karachentsev et al. (1985) as the “most peculiar” galaxy among 40 dwarf galaxies in the M81 group in their earlier survey (Karachentseva et al. 1985). The origin of the Garland is most likely associated with the tidal interactions of NGC 3077 and M81. Several numerical analyses have been presented to provide a dynamical history of the M81 + M82 + NGC 3077 group (Cottrell 1977; van der Hulst 1977; Killian 1978; Brouillet et al. 1991; Yun 1999). The most recent one by Yun (1999) was extremely successful in not only reproducing the spatial distribution of H I, but also its velocity field. Unlike in previous numerical simulations, Yun (1999) was able to produce the North Tidal Bridge, which runs between M82 and NGC 3077, by giving NGC 3077 its own disk (of nearly $10^9 M_\odot$) initially. The disk was then disrupted as the galaxy interacted with M81. Yun’s model predicts that the nearest approach of NGC 3077 and M81 was 280 Myr ago; for M82, the time since the pericenter is 220 Myr, which agrees very well with the estimated age of ongoing starbursts in M82. This strongly supports the idea that was first proposed by Toomre & Toomre (1972) that such tidal disruptions could “stoke the furnace,” enhancing starburst or active galactic nucleus activity.

Our $HST$ data suggest that the stars were formed in the halo of NGC 3077 during past 150 Myr, well after the calculated tidal encounter of this galaxy with M81. This suggests that the tidal interaction possibly triggered star formation in the halo region, perhaps from a condensed interstellar medium that was stripped from the main body of the galaxy as a result of the interaction. A composite H I/optical map shown in Figure 1 of Walter & Heithausen (1999) displays very well the fact that there is an offset between the center of H I concentration and the nucleus of NGC 3077, with the H I concentrated to the south of the galaxy. Our $HST$ fields were placed in the south-southwestern region of the halo, coinciding with the H I concentration. This, in conjunction with the ages of the upper main-sequence stars, suggests that the tidal interaction is indeed responsible for the recent star formation in the halo of NGC 3077.

Sakai & Madore (1999) presented the $HST$/WFPC2 observations of halo stars in M82. We reported the detection of intermediate-age asymptotic giant branch (AGB) stars, which again coincided with the H I concentrations in the M82 halo. Because of the quality of the photometry, which was not superior, and uncertainties caused by blending, we concluded that the detection of AGB stars was not 100% certain. Here in the case of NGC 3077, we observe a similar situation. However, in addition to some AGB stars, we also observe blue upper main-sequence stars, indicative of very recent star formation.

It is easy to argue that the AGB stars are likely blends of two or more fainter red stars. However, in order to make a bright blue upper main-sequence star, one needs two fainter blue stars; that is, the existence of upper main-sequence stars strongly suggests the presence of intermediate-age AGB stars.
stars, which signify more recent star formation, cannot be dismissed. For the case of the Garland in NGC 3077, it is conceivable that the recent star formation ( $< 150$ Myr) was triggered as a direct result of the tidal interaction of the galaxy with M81 (and M82). However, the theoretical dynamical model cannot constrain the interaction timescale by better than a factor of 2, suggesting another scenario in which these recently formed upper main-sequence stars were simply stripped from the main body of NGC 3077 and were not necessarily formed in the halo region. Had the photometric quality of the stars been better (i.e., had longer exposure times), we might have been able to separate the main-sequence stars from the blue He-burning (HeB) stars. Using the HeB stars, one can trace the star formation history back to $\sim 600$ Myr, which was the technique used by Dohm-Palmer et al. (1997) to study the recent star formation history in Sextans A. If we assume that these halo main-sequence stars were indeed tidally induced stars, we are then able to put a lower limit on the timescale at which the tidal interactions occurred.

As pointed out earlier, the Population II metallicity of some of the halo RGB stars in NGC 3077 is as high as $[\text{Fe/H}] \sim -0.7$, which is uncharacteristic for a dwarf galaxy of this size. We note, however, that even though the current size and luminosity of NGC 3077 might suggest that this galaxy is similar to SMC, the numerical simulations (Yun 1999) indicate that NGC 3077 had its own disk before interacting with M81. The total mass given to NGC 3077 in the best three-body numerical model was $2 \times 10^{10} M_\odot$. This mass is a couple of orders larger than that of a typical dwarf galaxy, inferring that fairly metal-rich, Population II RGB stars could have populated NGC 3077, and were then redistributed during the interaction with M81 and now occupy the halo. A slightly different scenario would be that the more metal-rich RGB stars were originally part of M81 and were pulled apart during their collision, eventually settling down in the halo of NGC 3077. It is impossible to determine the exact nature or origin of these halo stars, but on the other hand, we know from the deep $H\alpha$ maps of the M81 group that these galaxies have undergone a major interaction with each other; we cannot by any means regard NGC 3077 as an isolated dwarf galaxy. The metal-rich RGB stars in this small galaxy may be direct evidence that N3077 was originally a much larger spiral galaxy before the interaction.

Finally, another question of interest is whether the Garland is simply an interstellar medium with stars stripped from the main body of NGC 3077 or whether it is an independent dwarf galaxy. This is beyond the scope of this paper, requiring the photometric observation of the entire Garland region as well as the mapping of its velocity field.

This work was funded by the NASA LTSA program, NAS7-1260 to S. S.; B. F. M. was supported in part by the NASA/IPAC Extragalactic Database.

FIG. 8.—The $V$-band luminosity function of upper main-sequence stars. MSTO ages are indicated as well on this plot. A simple artificial star test suggests that our $V$-band photometry is complete down to $V \approx 25.5$ mag, which can also be seen in the luminosity function turnover at 25.5–26.0 mag.

The $V$-band luminosity function is complete down to $V \approx 25.5$ mag, which can also be seen in the luminosity function turnover at 25.5–26.0 mag.
