ABSTRACT

Orphan afterglows from short γ-ray bursts (GRB) are potential candidates for electromagnetic (EM) counterpart searches to gravitational wave (GW) detected neutron star or neutron star black hole mergers. Various jet dynamical and structure models have been proposed that can be tested by the detection of a large sample of GW-EM counterparts. We make predictions for the expected rate of optical transients from these jet models for future survey telescopes, without a GW or GRB trigger. A sample of merger jets is generated in the redshift limits $0 \leq z \leq 3.0$, and the expected peak $r$-band flux and timescale above the LSST or ZTF detection threshold, $m_r = 24.5$ and 20.4 respectively, is calculated. General all-sky rates are shown for $m_r \leq 26.0$ and $m_r \leq 21.0$. The detected orphan and GRB afterglow rate depends on jet model, typically $16 \lesssim R \lesssim 76$ yr$^{-1}$ for the LSST, and $2 \lesssim R \lesssim 8$ yr$^{-1}$ for ZTF. An excess in the rate of orphan afterglows for a survey to a depth of $m_r \leq 26$ would indicate that merger jets have a dominant low-Lorentz factor population, or the jets exhibit intrinsic jet structure. Careful filtering of transients is required to successfully identify orphan afterglows from either short or long GRB progenitors.

Key words: gamma-ray bursts: general

1 INTRODUCTION

The most promising candidate for the progenitor of short γ-ray bursts (GRBs) is the merger of a binary neutron star (NS) system or a NS black hole (BH) system (e.g. Eichler et al. 1989; Narayan et al. 1992; Mochkovitch et al. 1993; Bogomazov et al. 2007; Nakar 2007; Berger 2014). Such systems are candidate targets for gravitational wave detectors, and as such there has been a focus on potential electromagnetic (EM) counterparts to such mergers (Nissanke et al. 2013). Amongst the counterparts are the isotropic macro/kilo-nova (e.g. Li & Paczynski 1998; Barnes & Kasen 2013; Tanaka & Hotokuzaka 2013; Piran et al. 2013; Metzger & Fernández 2014; Tanaka et al. 2014, 2017; Barnes et al. 2016; Tanaka 2016; Metzger 2017), radio counterparts (e.g. Nakar & Piran 2011; Kytoku et al. 2014; Margalit & Piran 2015; Hotokuzaka & Piran 2015; Hotokuzaka et al. 2016), wide angle cocoon emission (Lazzati et al. 2017; Nakar & Piran 2017; Gottlieb et al. 2018; Kisaka et al. 2017), resonant shattering, merger-shock or precursor flares (Tsang et al. 2012; Kytoku et al. 2014; Metzger & Zivancev 2016), GRBs (e.g. Coward et al. 2014; Ghirlanda et al. 2016; Kathirgamanaraj et al. 2017; Jin et al. 2017), failed GRBs (fGRB) (Dermer et al. 2000; Huang et al. 2002; Nakar & Piran 2003; Rhoads 2003; Lamb & Kobayashi 2016, 2017), and off-axis orphan afterglows (e.g. Rossi et al. 2002; Granot et al. 2002; Zou et al. 2007; Zhang 2013; Lazzati et al. 2017; Sun et al. 2017). Some of these counterparts make promising potential transients for the next generation of optical survey telescopes e.g. Large Synoptic Survey Telescope (LSST) (LSST Science Collaboration et al. 2009), and Zwicky Transient Factory (ZTF) (e.g. Bellm 2014; Bellm & Kulkarni 2017).

Here we make predictions for transient rates in blind surveys (i.e. without a gravitational wave or γ-ray trigger), for orphan afterglows from short GRB jets and transients based on the expected excess as a result of low-Lorentz factor failed GRB jets (Lamb & Kobayashi 2016) and/or jets with extended wide structure (e.g. Lamb & Kobayashi 2017; Kathirgamaraj et al. 2017; Jin et al. 2017; Xiao et al. 2017). Different jet structures predict different emission properties, especially for off-axis viewing angles. Therefore, the detection rate of orphan afterglows will give an important constraint on the structure and dynamics of the jets. We consider only the transients from the afterglow due to the jet-IS M interaction; such transients will be associated with all jetted short GRB progenitor models and the jet af-
terglow, orphan or otherwise, will have a non-thermal spectrum. Where short GRBs are exclusively due to NS/BH-NS mergers, then additional transients will be associated; most notably a macro/kilo-nova that will have a red/infra-red frequency peak brightness that depends on the viewing angle, and an earlier blue/ultra-violet peak that will be apparent depending on the system inclination. Macro/kilo-nova emission will have a thermal spectrum and a very rapid decline after the peak.

In §2 we describe the merger jet parameters and models used and in §3 we describe the method for generating the cosmological population of merger jets. The results are described in §4, and discussed in §5. Concluding remarks are made in §6.

2 MERGER JET MODELS

We assume that the dominant progenitor for the short GRB population are relativistic jets from mergers (Levan et al. 2016). From the observed energetics of short GRBs a luminosity function can be determined (e.g. Wanderman & Piran 2015; Sun et al. 2015; Ghirlanda et al. 2016; Zhang & Wang 2017).

We generate seven populations of merger jets where we use a Wanderman & Piran (2015) redshift and luminosity function. Four have homogeneous jet structure models:

(i-iii) WP15$_{bc}$/16/26: With a coating phase bulk Lorentz factor $\Gamma = 100$ and a jet half-opening angle$^1$ of $\theta_j = 16 \pm 10^\circ$ (Fong et al. 2015). For population (i) $\theta_j = 6^\circ$, (ii) $\theta_j = 16^\circ$, and (iii) $\theta_j = 26^\circ$.

(iv) LK16: With a bulk Lorentz factor distribution for the population defined as $N(\Gamma) \propto \Gamma^{-2}$ with a range $2 \leq \Gamma \leq 10^3$ (Lamb & Kobayashi 2016). We assume each jet has a half-opening angle $\theta_j = 16^\circ$.

The final three jet populations use parameters that are described by the structured jet models in Lamb & Kobayashi (2017). These jets have a core angle $\theta_c = 6^\circ$ and a wider jet component to $\theta_j = 25^\circ$ in each case. For the structured jets the luminosity function is used to determine the power within the jet core:

(v) LK17t, two-component jets where the wider component $\theta_w < \theta \leq \theta_j$ has energy and Lorentz factor at 5% the core value

(vi) LK17p, power-law jets where the energy and Lorentz factor between the core and jet edge scale with angle from the core using a negative index power-law, $\propto (\theta/\theta_c)^{-2}$

(vii) LK17g, Gaussian jets where the energy and Lorentz factor follow a Gaussian function with angle to the jet edge, $\propto e^{-\theta^2/2\sigma^2}$

The existence of a jet edge for the structured jet models is motivated by relativistic magnetohydrodynamic simulations of neutron star mergers (e.g. Rezzolla et al. 2011; Dionysopoulos et al. 2015)

$^1$ Note that Ghirlanda et al. (2016) found this redshift distribution to indicate jet half-opening angles in the range $7^\circ \leq \theta_j \leq 14^\circ$, we use the wider angle and range to include the widest observations $\theta_j \geq 25^\circ$.

3 METHOD

We assume the short GRB rate$^2$ and luminosity function given in Wanderman & Piran (2015); note the event rate for this distribution varies with redshift, peaking at $z = 0.9$, and rapidly declines with increasing redshift ($R_{\text{GRB}} = 45 \ e^{(z-0.9)/0.39} \ \text{Gpc}^{-3} \ \text{yr}^{-1}$ where $z \leq 0.9$, and $R_{\text{GRB}} = 45 \ e^{-(z-0.9)/0.26}$ for $z > 0.9$). At redshifts below the peak, the event rate is consistent with that found by D’Antonv et al. (2014) and Sun et al. (2015). The luminosity function follows a broken power-law with the limits $5 \times 10^{53} \leq L_{\gamma} \leq 10^{55} \ \text{erg s}^{-1}$ and a brake at $2 \times 10^{52} \ \text{erg s}^{-1}$; at luminosities below the brake the power-law index is -1, and above the brake the index is -2. The luminosity function is defined with an interval d log $L_{\gamma}$. Note that we do not consider low-luminosity short GRBs, i.e. $L_{\gamma} < 5 \times 10^{50} \ \text{erg s}^{-1}$. The origin of low-luminosity short GRBs is not known, the low-luminosity population could represent an extension of the usual short GRB luminosity function to lower powers or a distinct population of low-luminosity short GRBs (e.g. Siellez et al. 2016). The afterglows from a population of low-luminosity GRBs would be intrinsically very faint and the redshift distribution of the observable sample limited to `local’ luminosity distances.

Using the short GRB rate ($\text{Gpc}^{-3} \ \text{yr}^{-1}$) and luminosity function, a correlation for isotropic equivalent energy and $\nu F_{\nu}$ spectral peak energy $E_{p}$ in Tsutsui et al. (2013), and assuming a spectral index $\alpha = 0.5$ and $\beta = 2.25$ (Gruber et al. 2014) with a broken power-law, we find the minimum $\gamma$-ray luminosity for a detectable short GRB and the rate at a given redshift. We assume a detection if the number of photons in the energy band $15$-$150 \ \text{keV}$ is $\geq 0.3 \ \text{ph cm}^{-2} \ \text{s}^{-1}$ (Band 2006). Using the minimum observable luminosity and the short GRB rate with redshift, the all-sky number of detectable short GRBs is $\sim 71 \ \text{yr}^{-1}$, however as noted by Bromberg et al. (2013), the Swift/BAT short GRB sample is contaminated by non-merger (collapsar) short duration GRBs, the fraction of merger short GRBs is $\sim 60\%$. Using a detection rate of $\sim 6 \ \text{yr}^{-1}$ the effective field-of-view for Swift/BAT is $\sim 1.06 \ \text{sr}$, this is less than the BAT partially coded field-of-view $\sim 1.4 \ \text{sr}$ (Baumgartner et al. 2013). The Swift/BAT duty cycle, the sensitivity of the partially coded field-of-view, or the exact fraction of merger short GRBs may explain this discrepancy. The all-sky rate for short GRBs is used to normalize the Monte Carlo merger jet samples.

For each model (i-vii), $10^6$ merger-jets are generated. Each jet has a random isotropically distributed inclination $i$ to the line-of-sight and a random redshift $z$ using the short GRB redshift distribution. The jet energetics, and bulk Lorentz factor depend on the model parameters. The prompt emission is highly beamed and only detectable for typical cosmological distances and $\gamma$-ray energies from jets inclined within the jet half-opening angle. The $\gamma$-ray photon flux at the detector for a jet inclined within the half-opening angle is calculated considering the jet luminosity. A correlation between the $\gamma$-ray luminosity and spectral peak energy for short GRBs is used to determine $E_p$ (e.g. Yonetoku et al. 2004; Ghirlanda et al. 2009;
Zhang et al. 2012; Tsutsui et al. 2013). We use the same GRB detection criteria as that used to estimate the all-sky Swift/BAT short GRB rate.

Using the fireball model (Piran 1999) and an assumed \(\gamma\)-ray efficiency \(\eta\) for the prompt emission, the isotropic equivalent blast energy can be found from the \(\gamma\)-ray luminosity \(L_\gamma\) and timescale \(T_{90}\). The jet kinetic energy \(E_k = L_\gamma T_{90}/(1/\eta - 1)\) is dissipated in shocks that form as the jet decelerates in the ambient medium giving rise to an afterglow. The temporal evolution and peak afterglow flux of a GRB follows Sari et al. (1998, 1999), where the peak flux is \(F_p \propto n^{1/2} \epsilon_B^2 E_k D^{-2}\), where \(n\) is the ambient number density, \(\epsilon_B\) is the microphysical magnetic parameter, and \(D\) is the luminosity distance.

For an off-axis observer, at an inclination greater than the jet half-opening angle \(\theta_j\), the observed flux is reduced by relativistic effects. The flux at a given observer frequency \(\nu\) becomes \(F_\nu(t) = a^2 F_\nu(0, a t)\), where \(a = \delta(i)/\delta(i = 0)\) and \(\delta = [\Gamma(1 - \beta \cos i)]^{-1}\) is the relativistic Doppler factor; \(\Gamma\) is the bulk Lorentz factor, and \(\beta\) is the jet velocity relative to the speed of light (Granot et al. 2002). Note that this relation is valid for a point source only and that for a jet with a defined opening angle the relativistic beaming factor for the flux is \(\sim a^2\) for \(i \leq 2\theta_j\), and the angle used to calculate the relativistic Doppler factor is \(i - \theta_j\) where \(i > \theta_j\) (Kumar & Panaitescu 2000; Ioka & Nakamura 2001).

For all jets we use the method in Lamb & Kobayashi (2017), with the relevant jet structure model to generate on/off-axis afterglows for the population of jets. The ambient density is assumed to be \(n = 0.1\) cm\(^{-3}\), microphysical parameter \(\epsilon_B = 0.1\), \(\epsilon_B = 0.01\), particle distribution index \(p = 2.5\), and \(\gamma\)-ray radiation efficiency \(\eta = 0.1\). For each population the normalized number of Swift/BAT GRBs and orphan afterglows are counted.

Using the distribution of peak afterglows from a given model, and a transient survey telescope’s per night coverage, the number of transients with or without a GRB, that have an optical counterpart brighter than the survey’s detection threshold can be found. For transients in our sample that are brighter than the LSST/ZTF survey threshold, \(r\)-band magnitude \(\sim 24.5\) (20.4), we determine that the number of transients that are brighter than this limit for \(\geq 4(1)\) days. This ensures a minimum of two detections within the proposed cadence. For LSST we use a survey rate of \(\sim 3300\) deg\(^2\) night\(^{-1}\), covering \(\sim 0.08\) of the whole sky per night; for ZTF the survey rate is \(\sim 3760\) deg\(^2\) hour\(^{-1}\), where the average night is 8h 40m (Bellm 2014). ZTF will cover \(\sim 0.09\) of the whole sky per hour, and considering the observable fraction of the sky per night, will cover \(\sim 22500\) deg\(^2\) night\(^{-1}\) or \(\sim 0.55\) of the whole sky per night with a 1 day cadence.

4 RESULTS

The rate of afterglow transients for each model is shown in Table 1. The various models are described in §2. For LK17t, LK17p and LK17g (v-vii), the opening angle at which a GRB is detectable depends on the distance, luminosity and inclination of the source. For the WP15 (i-iii) and LK16 (iv) models, a GRB is typically only detectable for inclinations that are less than the jet half-opening angle, \(i < \theta_j\).

Figure 1 shows the number of afterglow transients per square degree per year brighter than a given \(r\)-band magnitude from merger jets. Each model is indicated by a different colour and line style as described in the figure caption. Each distribution is for both GRB and orphan afterglows (the value in square brackets in Table 1). We assume a fixed ambient density for all events of \(n = 0.1\) cm\(^{-3}\). However, the density for short GRB environments has a broad range and the peak flux depends on the ambient density as \(\propto n^{1/2}\). As \(40\%\)–\(80\%\) of the short GRB population, where \(\epsilon_B = 0.01\), have \(n > 0.1\) cm\(^{-3}\) (Fong et al. 2015), then considering the
full ambient density range, the presented results are not significantly changed.

The homogeneous jet models with a fixed initial Lorentz factor WP15 (i,ii,iii) produce detectable GRBs, where the detector has our parameters and sensitivity, for an all sky rate of Swift/BAT detectable short GRBs of $\sim 71 \text{ yr}^{-1}$. The first value in each column is for orphan afterglows only, the values in square brackets are for GRB and orphan afterglows combined. The all-sky rates less than a given magnitude have an associated uncertainty of $\sim \pm 0.7 \text{ deg}^2 \text{ yr}^{-1}$. The LSST and ZTF detection rate is based on the mean timescale a transient is brighter than the telescope threshold.

| Model | $\leq 26$ | $\leq 24.5$ | $\leq 21$ | $\leq 20.4$ | $\langle T_{\text{LSST}} \rangle$ | LSST | $\langle T_{\text{ZTF}} \rangle$ | ZTF |

### 5 DISCUSSION

We have generated a Monte Carlo distribution of merger jets for each of the jet models considered: a population of homogeneous jets with a jet half-opening angle of 6°, 16°, or 26°; a population of merger jets that have an independent Lorentz factor following a negative index power-law distribution; and three structured jet models, all with a core value of 6° and a jet edge at 25°. The merger jets follow a redshift distribution for merger (non-collapsar) short GRBs and have a random isotropic redshift distribution. For each event the $\gamma$-ray photon flux at the detector in the energy band 15–150 keV is determined, if the flux is greater than the threshold value then a GRB is detectable. Each population of merger-jets is normalized by the all-sky rate of Swift/BAT detectable short GRBs.

The fraction of on-axis events $i < \theta_j$ will follow the probability distribution for a randomly oriented bi-polar jet system with the jet half-opening angle $\theta_j$, i.e. $1 - \cos \theta_j \sim \theta_j^2/2$. Not all on-axis events will produce a detectable GRB or afterglows above the detection threshold. For all models considered this is due to a combination of luminosity, distance to a merger, and spectral peak energy. For the LK16 and structured jet models, the failed GRB fraction is higher due to suppression of the prompt emission in the low-$\Gamma$ energy jet/components.

Forward shock afterglow transients from short GRBs, on-axis failed GRBs, and off-axis orphan afterglows are detectable by both the LSST and ZTF. The rate for both LSST and ZTF detectable transients depends on the nature of the jets in a population of mergers. Where the jet Lorentz factor varies from jet to jet, only a small fraction of the merger jets, when viewed on-axis, will produce a detectable GRB (e.g. Lamb & Kobayashi 2016). Afterglows are typically fainter for a population of low-$\Gamma$ failed GRBs, this is due to the later deceleration time for the jet where $t_{\text{dec}} \propto \Gamma^{-8/3}$, and the lower characteristic synchrotron frequency, $\nu_{\text{m}} \propto \Gamma^4$, meaning the optical peak flux is lower than the maximum synchrotron flux as $\nu_{\text{obs}} > \nu_{\text{m}}$ at the peak time. This is reflected in the orphan afterglow rate being $\sim 2 - 3 \times$ larger for LK16 model (iv) than for WP15b model (ii), where $\Gamma = 100$ for all events.

For jets with structure, the orphan afterglows are typically brighter than the orphan afterglows for a population of homogeneous jets (Lamb & Kobayashi 2017). Structured jets have higher latitude jet components with a low-$\Gamma$ that can suppress a GRB for an observer at these inclinations.
thus structured jets can produce a larger fraction of orphan afterglows where the inclination is less than the jet half-opening angle. These orphans are typically brighter than a homogeneous jet described by the γ-ray bright region of a structured jet. However, for the two-component jet LK17 model (v) it is clear from Figure 1 that the rate of transients is ∼ 80% that of the rate for a homogeneous jet population with θj = 6°, WPI15 model (iii). The two-component model will typically have a γ-ray bright core, θj = 6°, and an extended ‘sheath’ that generally fails to produce detectable GRBs. For model (iii), θj is equivalent to the core size in the two-component model. Due to the two models extended structure, GRBs are observable at i > θj in jets where the core luminosity is very high or the merger is nearby. Therefore the fraction of GRBs from this model is also that for the 6° homogeneous jet model and thus when the distributions are normalized the total number of mergers is smaller.

To consider the fraction of afterglows detected by blind sky surveys, the typical time period for which a transient is brighter than the limiting magnitude is determined. For the LSST(ZTF) limit of 24.5(20.4) the typical timescale is shown in Table 1. The product of the all-sky rate (deg−2 yr−1), the per night survey field-of-view (deg2 day−1), and the typical timescale for a transient (day) gives the expected rate of detectable transients for a survey. For LSST the chance of detecting an orphan afterglow from a merger jet is reasonable, 5 ≲ RAG ≲ 70 yr−1, depending on the jet model. If we consider both orphan and GRB afterglows the rate increases, 16 ≲ RAG ≲ 76 yr−1. For ZTF the rate of detected orphan afterglows from merger jets is low, 0.5 ≲ RAG ≲ 3.6 yr−1. The combined orphan and GRB afterglow rate is more promising, 2 ≲ RAG ≲ 8 yr−1. However, in each case, the afterglow transients are rarely brighter than the detection threshold for longer than the cadence.

The differentiation between merger-jet origin orphan afterglows and collapsar or long GRB jet orphans will be difficult. Ghirlanda et al. (2015) predicts a rate of RAG ∼ 50 yr−1 for the LSST from long-GRB jets. For faint transients, the peak flux may not be brighter than the host galaxy, magnitude ∼ 24 − 27 (Berger 2014). In such a case the detection of a transient will depend on the survey angular resolution and the image subtraction technique. However, short GRBs can be hostless or have typically large offsets from the bright core or star forming regions, but in such cases the ambient density is low and the peak flux will be fainter. Long GRBs are typically associated with star-forming galaxies and regions (e.g. Bloom et al. 1998; Djorgovski et al. 1998; Fruchter et al. 2006), making faint orphan transients from long GRB jets more difficult to detect. Short GRB host galaxies systematically have an older stellar population, have a lower star-formation rate, and a higher metallicity than the host galaxies for long GRBs (Berger 2014). Note however that short GRB host galaxies can be both early- and late- type galaxies. Additionally, simulations performed by O’Shaughnessy et al. (2017) suggest that short GRB merger progenitor systems are overproduced by dwarf galaxies; these galaxies are typically faint with surface brightness −14 ≲ M_B ≲ −10 (Sabatini et al. 2003), approximately magnitude 28–32 at z = 0.5. Alternatively, by considering the natal kick velocities of NS-NS systems, the fraction of hostless short GRBs, and the dark matter potential well of galaxies, Behroozi et al. (2014) found that short GRBs are expected to be associated with galaxies that have a stellar mass (5 ± 3) × 10^10 M⊙. The differences in the host galaxy and location within the host galaxy may be used to distinguish between the progenitor of GRB-less transients.

The predicted low detection rates for merger jet transients can result in confusion not only between a collapsar jet and merger jet origin but also, and perhaps dominantly, from other astrophysical transients. Flares from active galactic nuclei (AGN), tidal disruption events (TDEs), and rapidly evolving faint supernovae (SNe) are amongst the confusion sources for fast and faint extragalactic transients. For these events, the location within the host galaxy can help distinguish the origin, where AGN and TDEs are expected to be located within the core of a galaxy. Spectroscopy, or colour evolution that can trace the underlying spectrum, are required to reliably distinguish between a non-thermal jet afterglow transient and a SNe or SN-like transients. However, a thermal transient that either precedes or follows the nonthermal jet will indicate a merger origin, see discussion below.

By considering the other associated transients for a NS/BH-NS merger i.e. resonant shattering flares or impact flares for NS mergers (Tsang et al. 2012; Kyutoku et al. 2014) or SNe for long GRBs, the origin of the orphan afterglow may be additionally constrained for nearby events. With the development of next generation gravitational wave detectors e.g. the Einstein Telescope (ET) (Punturo et al. 2010), the volume within which a NS/BH-NS merger can be detected increases. Coincident survey transients (e.g. Scolnic et al. 2017), within the ET detection horizon z ∼ 0.5, and GW merger signals will be key to characterising the growing number of objects in the transient sky. The rate of transients at z < 0.5, with m_z ≤ 26, for our models is (0.2 < R_{AG} < 0.5) × 10^{-3} deg^{-2} yr^{-1}, and a mean rate <R_{AG} < 0.5> ∼ 3 × 10^{-4} deg^{-2} yr^{-1}. For each model the rate is: (i) 4.5, (ii) 0.6, (iii) 0.2, (iv) 6.8, (v) 4.0, (vi) 2.4, and (vii) 5.1 where the units are ×10^{-2} deg^{-2} yr^{-1}. These deep survey rates for a field-of-view 3300 deg2 are: (i) 3.0(22.2), (ii) 0.5(20.4), (iii) 0.2(19.6), (iv) 12.6(114.6), (v) 3.3(24.2), (vi) 2.4(44.5), (vii) 2.4(23.7) yr−1 where the number in brackets is without the redshift condition.

The rate of orphan afterglows from long GRBs is higher than that for short GRBs due to the difference in the occurrence rate of either transient. Long GRBs typically have jet half-opening angles θ_j > 6° (Ghirlanda et al. 2015). The peak afterglow for a highly inclined system at i > θ_j decreases rapidly with increasing angle; for long GRB jets associated with SNe, the peak flux rapidly falls below the peak of the accompanying SN where the absolute magnitude is typically M ∼ −19. If the majority of long GRB jets are from core-collapse SNe then the orphan afterglow will be hidden by the SN for systems inclined at i ≥ 20° away from the jet

---

4 This depends on the K-corrected luminosity of the SN (Prentice et al. 2016). GRB afterglows are brighter over a broader spectrum than SNe due to the non-thermal nature of the emission, the off-axis GRB afterglow spectrum is increasingly shifted to lower frequencies as the observation angle increases, this effectively contributes to the reduction in the observed off-axis flux for an orphan afterglow at optical frequencies.
axis (Kathirgamaraju et al. 2016), this will reduce the number of detectable orphan afterglows from long GRBs, where it is assumed that all long GRBs have narrow homogeneous jets. Using the condition that an orphan afterglow from a long GRB must be inclined $i \leq 20^\circ$, the fraction of the total population could be lower than the predicted 50 yr$^{-1}$.

Figure 2 shows how the absolute magnitude for an observer in the $r$-band changes with inclination for a homogeneous jet with $\theta_i = 16^\circ$ and a range of isotropic equivalent energies $5 \times 10^{48} \leq E_{iso} \leq 10^{52}$ erg. The peak $r$-band macro/kilo-nova flux is shown as a red line, where the range is the observed diversity (Gompertz et al. 2017) which agrees with the predicted range for macro/kilo-nova peak magnitudes in Tanaka & Hotokezaka (2013) and Barnes & Kasen (2013). For jets from mergers, the associated macro/kilo-nova emission, although isotropic, is generally considered to be fainter for increasing observation angles (e.g. Tanaka et al. 2014; Tanaka 2016; Metzger 2017; Wollaeger et al. 2017). The macro/kilo-nova associated with GW170817 is shown as a red triangle at an inclination of $28^\circ$ (see for example: Abbott et al. 2017; Coulter et al. 2017; Drout et al. 2017; Evans et al. 2017; Metzger 2017; Murguia-Berthier et al. 2017; Pian et al. 2017; Smartt et al. 2017; Tanaka et al. 2017; Tanvir et al. 2017, etc.). Macro/kilo-nova will typically peak in the $r$-band $\lesssim 5$ days after the merger for an observer at any inclination. However, the jet afterglow peak flux time is much later for an off-axis observer (days to months) than for an on-axis observer (minutes to hours). Where an orphan afterglow peaks $\lesssim 1$ day or $\gtrsim 5$ days, a survey telescope may have two opportunities to observe the merger, one from the afterglow and a second from the macro/kilo-nova; the afterglow transient will typically fade much slower than that from a macro/kilo-nova and will have a non-thermal spectrum. Thus, even if the transients have coincident peaks, the afterglow will fade more slowly than the macro/kilo-nova. Additionally, due to the broadband nature of the afterglow a radio transient should accompany the optical, possibly peaking at a later time depending on the inclination of the system.

The orphan afterglow population may be dominated by low-luminosity GRBs. Such low-luminosity GRBs form a distinct population (Wanderman & Piran 2010) where the rate is greater than that for long GRBs. The afterglow from low-luminosity GRBs is fainter than that for long GRBs (Barniol Duran et al. 2015), but the lower Lorentz factor of the ejecta means that any off-axis emission will have a reduced beaming effect. Where an orphan afterglow is brighter than the accompanying SNe, then low-luminosity GRB orphan afterglows may dominate the blind survey population.

The jets that produce long GRBs may exhibit the same structure or dynamical diversity as proposed for merger jets, the number of detectable orphan afterglows from long GRB or collapsar jets will be higher than that predicted by assuming homogeneous structured jets. The increased rate of orphan transients from either collapsar jets or merger jets would indicate the presence of intrinsic jet structure or a dominant population of low-$\Gamma$ jets. If long GRB jets follow the latter, i.e. a dominant low-$\Gamma$ population (Hascoët et al. 2014), the rate of orphan afterglows from collapsar jets would be higher by a similar fraction to that demonstrated here for merger jets with the LK16 model (iv). The lightcurve of an on-axis orphan afterglow will appear phenomenologically the same as a GRB afterglow, i.e. a power-law decay, $\propto t^{-1}$ with an observable break at late times. Whereas an off-axis orphan afterglow would decay with a steep, $\propto t^{-2}$, decline with no jet-break.

We used a population of mergers that follow a lognormal time delay redshift distribution (Wanderman & Piran 2015). If NS/BH-NS mergers follow a power-law time delay distribution that peaks $z \sim 1.5$–2, then a higher fraction of the short GRB population would go undetected due to the large luminosity distance. The observation of a host for short GRB 111117A at $z = 2.211$ could challenge the lognormal time delay model, although this redshift is still within the lognormal limits, the probability is $\sim 2$ orders of magnitude lower than for the peak at $z = 0.9$ (Selsing et al. 2017). De-
detectable orphan afterglows from a power-law time delay redshift distribution will follow the rates predicted here where $m_r \lesssim 23$. A significant excess would exist at very faint magnitudes, $m_r > 26 - 28$, where the population distribution peaks at a redshift $z \gtrsim 1.5$. The peak of the redshift distribution can be traced by the faint transients. For a discussion of a short GRB population with such a distribution see Sun et al. (2015) and Ghirlanda et al. (2016).

6 CONCLUSIONS

We have shown that the rate of orphan afterglows from merger (non-collapsar) short GRBs detectable by the LSST is $5 \lesssim R_{OA} \lesssim 70$ yr$^{-1}$, where the rate is $\sim 7.3$ yr$^{-1}$ for a population of homogeneous jets with $\theta_j = 16^\circ$. Where GRB afterglows are included, the rates become $16 \lesssim R_{AG} \lesssim 76$ and $\sim 19$ yr$^{-1}$ for homogeneous jets with $\theta_j = 16^\circ$. The ZTF detection rate for orphan afterglows from short GRBs is low $0.5 \lesssim R_{OA} \lesssim 3.6$, the rate for afterglows with or without a Swift/BAT detectable GRB is $2 \lesssim R_{AG} \lesssim 8$ yr$^{-1}$, and $\sim 4.2$ yr$^{-1}$ for a population of homogeneous jets with $\theta_j = 16^\circ$.

For populations of jets narrower than $\theta_j = 16^\circ$, the rate of orphan afterglows increases. For LSST the orphan afterglow rate from a population of narrow short jet GRBs is $\sim 13.4$ yr$^{-1}$. This increase is due to the increased rate in the parent merger population due to the normalization required to produce the detectable all-sky Swift/BAT non-collapsar GRB rate.

If the population of jets that produce short GRBs is dominated by jets with a low-$\Gamma$, then the rate of orphan afterglows will increase significantly, $\sim 70$ yr$^{-1}$ for LSST and $\sim 3.6$ yr$^{-1}$ for ZTF. Where these jets result in failed-GRBs and are viewed within the jet half-opening angle, the lightcurve will appear phenomenologically the same as an on-axis GRB afterglow lightcurve.

If jets exhibit intrinsic structure, where the jet energetics extend beyond a homogeneous core to a defined edge, then the rate of orphan afterglows is greater than that for a homogeneous population; with the exception of the two-component jet structure when compared to the narrowest homogeneous jet population.

If LSST modifies the observation strategy from a fast survey to a deep-drilling field, then the obtainable sensitivity will increase. By focusing on a single field the potential to detect the same transient with multiple observations increases and with this the ability to identify orphan afterglows. As shown in Figure 1 and Table 1, the rate of detectable merger-jet transients increases significantly from a limiting magnitude of 24.5 to 26 for a population of narrow jets, a jet population dominated by low-Lorentz factors, or jets with intrinsic structure.

The structured or dynamical models tested here could equally be applied to collapsar or long GRB jets. The observed rate of orphan afterglows from such jets would increase by a similar fraction for each case. Careful filtering of transients is required to successfully identify an orphan afterglow from either short or long GRB jets. Orphan afterglows fade rapidly and will rarely be above the detection threshold $> 1$ day, single point candidate identification and fast targeted follow-up will be required.

ACKNOWLEDGEMENTS
