INTRODUCTION

Schizophrenia (SCZ) is a severe psychiatric disorder with a prevalence of 1% worldwide. Schizophrenia is a complex disease which many genes and environmental factors are involved in its pathogenesis. Its etiology is still unclear. Among numerous physiologic mechanism of Schizophrenia, dopamine hypothesis is the most accepted one which suggests excessive activity of dopamine function or drugs increasing dopamine function may induce psychotic symptoms. And in clinical practice, the dopaminergic receptor antagonist (e.g., chlorpromazine, clozapine, risperidone, etc) were extensively used to treat Schizophrenia.

Many GWAS studies and related studies have detected genetic factors may be associated with SCZ, which indicates a genetic background of schizophrenia. One of these genes is the VMAT2 gene, which is located at 10q25. A suspected locus of schizophrenia detected by a systematic genome wide linkage study had a LOD score of 3.87. VMAT2 is an integral membrane protein that transports monoamine from the cytoplasm to the vesicles. VMAT2 protein mainly expresses in the brain and plays an important role in the transmission of monoamine function, including dopamine.

The Gene Polymorphism of VMAT2 Is Associated with Risk of Schizophrenia in Male Han Chinese

Objective To investigate the association between gene polymorphism of vesicular monoamine transporter type 2 (VMAT2) and schizophrenia in Han Chinese population.

Methods 430 patients with schizophrenia and 470 age-sex matched controls were recruited from four mental health centers. All patients were diagnosed by two psychiatrists based on the Structured Clinical Interview for DSM Disorders (SCID). The ligase detection reactions (LDR) method was used to assess the polymorphism of the two SNPs (rs363371 and rs363324) of VMAT2.

Results No associations of two SNPs with schizophrenia was found. When we stratified males and females for the analysis, we found that that in the recessive model of rs363371, there was an obvious significant association between rs363371 and schizophrenia in males (OR=0.564, 95% CI=0.357–0.892, p=0.014) but not females. For the association between rs363324 and schizophrenia, no association was found in either males or females. No association was found when stratifying early-onset schizophrenia and late-onset schizophrenia.

Conclusion Our findings indicate that both rs363371 and rs363324 were not associated with schizophrenia, while it seemed that the AA genotype of rs363371 plays a protective effect in male Chinese in developing schizophrenia.

Psychiatry Investig 2020;17(11):1073-1078

Key Words Schizophrenia, VMAT2, Gene polymorphism, Male, Han Chinese.
Recently, an Italian study reported that two SNPs (rs363371, rs363324) in the promoter region of VMAT2 are associated with Parkinson’s disease. Since dopamine hypothesis was the common base of both Schizophrenia and Parkinson’s disease. For patients with Parkinson’s disease, the deficiency of dopamine in substantia nigra accounts for the main clinical characteristics of the motor symptoms in Parkinsonism. Nevertheless, the new revised dopamine hypothesis of schizophrenia is the imbalance of dopamine function in different brain regions, which is the hyperactive dopamine transmission in the mesolimbic areas but hypoactive dopamine transmission in the prefrontal cortex. Interestingly, both Schizophrenia and Parkinson’s disease have shared some common genetic risk factors such as MMP9, MAOB, COMT, etc.

However, it has not been clear the association of VMAT2 SNP with schizophrenia. Thus, as the shared pathogenic mechanism and genetic factors between schizophrenia and Parkinson’s disease, we conducted a case-control study to explore the association between VMAT2 gene polymorphism and Schizophrenia in Han Chinese population.

**METHODS**

**Subjects**

A total of 430 (male185 43.02%; mean age 41.27±14.40 years, mean onset age 25.05±8.69 years) patients with SCZ were recruited from four psychiatric disorder centers: The Second Xiangya Hospital of Central South University, located in central China; West China Hospital of Sichuan University, located in southwest China; and the Third Affiliated Hospital of Sun Yat-sen University and Jining Mental Health Hospital, both located in east China. All patients were diagnosed by two psychiatrists based on the Structured Clinical Interview for DSM Disorders (SCID) and DSM-IV criteria. Patients who were older than 18 at SCZ onset were subdivided into late-onset SCZ (LOSCZ; n=290; mean age at onset, 27.71±7.96 years); the others were as early-onset SCZ group (EOSCZ; n=140; mean age at onset, 15.57±2.05 years). The control group for SCZ patients comprised 497 Han Chinese (190 males, 280 females; mean age, 42.33±12.45 years). The protocol of the study was approved by the Ethics Committees of all four hospitals involved in this research (No [2015]2-23), all the written informed consents were obtained from all the subjects involved in this study.

**Genotyping**

Genomic DNA was obtained from peripheral leukocytes by the classic Phenol-chloroform DNA extract method. All the genotyping experiments were done by the Shanghai BioWing Applied Biotechnology Company using ligase detection reactions (LDR). The target DNA sequences were amplified using a multiplex PCR method. The primary information for rs363371 and rs363324 listed in Supplementary Table 1 (in the online-only Data Supplement). After the completion of the amplification, 1 μL of Proteinase K (20 mg/mL) was added, then heated at 70°C for 10 min and quenched at 94°C for 15 min. The ligation reaction for each subject was carried out in a final volume of 20 μL containing 20 mM Tris-HCl (pH 7.6), 25 mM potassium acetate, 10 mM magnesium acetate, 10 mM DTT, 1 mM NAD, 0.1% Triton X-100, 10μL of MultiPCR product, 1 pmol of each discriminating oligo, 1 pmol of each common probe and 0.5 μL of 40 U/μL Taq DNA ligase (New England Biolabs, USA). The LDR was performed using 40 cycles of 94°C for 30 s and 63°C for 4 min. The fluorescent products of LDR were differentiated by ABI sequencer 377.

**Statistical analysis**

Values for age were represented by the mean±standard deviation (SD), and the gender, allele and genotype were described as percentages. Allele and genotype frequencies were determined by direct counting of VMAT2 alleles. Concordance of genotype distribution was verified by Hardy-Weinberg equilibrium (HWE) and then evaluated with the chi-square test. Associations between gender, allele and genotype were also assessed by the chi-square test. Age differences between the three groups were assessed by the t-test. A twotailed p value <0.025 was considered significant. Power calculations were carried out using “Power and Sample Size Program.” We recruited a study with 430 case patients and 470 control patients. Prior data indicated that the probability of exposure among controls was 0.302. If the true odds ratio for disease in exposed subjects relative to unexposed subjects was 0.284, we rejected the null hypothesis that this odds ratio

| Characteristic          | SCZ (n=430) | Controls (n=470) | Comparison* |
|-------------------------|-------------|-----------------|-------------|
| Age years, mean±SD     | 41.27±14.40 | 42.33±12.45     | t=0.18, p=0.24 |
| Sex (N)                 |             |                 |             |
| Male                    | 185         | 190             | 0.80, 0.63-1.02, 3.14, 0.08 |
| Female                  | 245         | 280             |             |

*unless otherwise indicated, the values indicate: odds ratio, 95% confidence interval, χ², p value. SD: standard deviation
sive model, there was an obvious significant difference between the male SCZ group and the male controls (OR=0.564, 95% CI 0.357–0.892, p=0.014). There were not any statistical significant between the SCZ group and the control group, the SCZ female group and controls, the EOSCZ, LOSCZ and the control group (Table 2). For the other SNP rs363324, there were no the obvious differences between the SCZ group and the control group and between the subgroups in both dominant and recessive models (Table 2). For the two SNPs, the allele frequencies were not different in any compared groups (Supplementary Table 2 in the online-only Data Supplement). The linkage disequilibrium D’ value between rs363371 and rs363324 was 0.334, suggesting a strong recombination event. Thus we conduct a Haplotype analysis, in which haplotypes with frequencies <0.03 were excluded, identified the three haplotypes equals 1 with probability (power) 1.0. The Type I error probability associated with this test of this null hypothesis was 0.05. We used an uncorrected chi-squared statistic to evaluate this null hypothesis. The SPSS 17.0 was used for all statistical analyses. Haplotypa1075

|         | G-G        | 205 (23.9) | 214 (23.0)     | 0.216 | 0.642 | 1.053 (0.846–1.311) |

*only haplotypes with a frequency of p>0.03 were considered in the analysis. A,G, indicates the allele of rs363371; A,G indicates the allele of rs363324. SCZ: schizophrenia, OR: odds ratio, CI: confidence interval

RESULTS

From our data, there were no significant differences between SCZ and Controls for gender, age (Table 1). For the SNP rs363371 there were no obvious significant differences of the distribution between the SCZ group and the control group (OR=1.607, 95% CI 0.761–1.495, p=0.709) or between the subgroups in dominant model (Table 2). While in the recessive model, there was an obvious significant difference between the male SCZ group and the male controls (OR=0.564, 95% CI 0.357–0.892, p=0.014). There were not any statistical significant between the SCZ group and the control group, the SCZ female group and controls, the EOSCZ, LOSCZ and the control group (Table 2). For the other SNP rs363324, there were no the obvious differences between the SCZ group and the control group and between the subgroups in both dominant and recessive models (Table 2). For the two SNPs, the allele frequencies were not different in any compared groups (Supplementary Table 2 in the online-only Data Supplement). The linkage disequilibrium D’ value between rs363371 and rs363324 was 0.334, suggesting a strong recombination event. Thus we conduct a Haplotype analysis, in which haplotypes with frequencies <0.03 were excluded, identified the three haplotypes.
A-G, G-A, and G-G. None of these haplotypes showed a significant association with SCZ (Table 3).

DISCUSSION

Our data did not detect an association of schizophrenia with two SNPs in the VMAT2 gene found in PD. Our study was consistent with a previous study that failed to detect an association between VMAT2 and SCZ, nonetheless that study did not including the two SNPs of our study.17 Interestingly, we did find the AA genotype of rs363371 as a protective allele for male Han Chinese from developing SCZ (OR =0.564, 95% CI 0.357 to 0.892, p=0.014). And this locus, located in the promoter of VMAT2, is potentially functional. It is in linkage disequilibrium with locus rs2619096, which doubles the activity of the VMAT2 promoter.18

Although many studies have shown a relationship between VMAT2 pathophysiology of neuropsychiatric diseases including schizophrenia,19 mood disorders,20 methamphetamine neurotoxicity,21 In patients with SCZ, it was reported that the density of VMAT2 protein increased in platelets, which may indicate a schizophrenia-related hyperactivity of the monoaminergic system or an adaptive response to chronic drug treatment.22 In a 14-3-8epsion hetero KO mice model of schizophrenia, the expression of VMAT2 was increased significantly in the hippocampus, indicating a possible pathophysiology of schizophrenia includes a monoaminergic transmission abnormality.23 Recently, a study showed that genetic variation in VMAT2 may be linked to alterations in cognitive functioning underlying psychotic disorder.24 VMAT2 SNPs effect on promoter activity or mRNA abundance25,26 which affects VMAT2 expression. Based on the above results, we speculated that VMAT2 gene polymorphism may be a risk factor for schizophrenia. Therefore, the study on the association between VMAT2 gene polymorphism and schizophrenia should amplify the sample size, increase the locus and multicenter studies.

Interestingly, our study showed a significant difference of AA genotype of rs363371 between the male patients with SCZ and male controls but not between female patients with SCZ and female controls. It seems contrary to a GWAS research which supports the idea that there is no strong sex-specific genetic risk factors exist for schizophrenia.27 But indeed, there were some other evidence supports the potential sex-specific genetic factors. One case-control study showed a gender difference of genetic factors, in which interleukin 1 receptor antagonist protein (IL1Ra) and IGF2BP2 were associated with SCZ in male population but not in female.28,29 C allele and CC genotype of rs253 was reported a confer risk for schizophrenia in men.30 A male-specific association was also be reported with SNP rs62621676 in a UK case-control study.31 While, there were more female-specific genetic factors. Two case-control studies from China showed that a high-affinity neureotensin receptor 1 (NTR1) gene polymorphism and estrogen receptor 1 (ESR1) gene polymorphism were increased in the risk of developing SCZ in female Chinese population.21,31 A GWAS study found a female-specific association with rs7341475 in the reelin (RELN) gene.34 Most interestingly, a study showed that in the same gene, different SNPs conduct different sex-specific effects, e.g., SNPs rs3891636, rs7728773, rs2189663,rs3864283, and rs2526303 of HINT1 gene were significantly different with controls among the female subjects alone, whereas SNP rs7735116 was significant among males alone.35 These studies indicated that sex-specific genetic risk and protective factors may exist in SCZ.

To our knowledge, this is the first case-control study that aimed to detect a potential relationship between SCZ and the two potentially functional SNPs of VMAT2 in Chinese population. Nevertheless, our results have some limitations. First, the relative small sample size may confer a low statistical power (the power for rs363371 was 80.8% while for rs363324 was only 5.1%). Second, we only selected two SNP in the promoter region, which may have missed other potential risk SNPs. Third, we did not take other risk factors associated with SCZ (e.g., environmental and social factors) into consideration. Moreover, a recent study found that VMAT2 was associated with Tardive dyskinesia (TD), an involuntary movement disorder affecting up to 25% of patients receiving long-term first-generation antipsychotic treatment.36 Thus, the gene-medical treatment should be taken into consideration in the future study.

In conclusions, our study found that rs363371 and rs363324 were not associated with SCZ, while it seems that the AA genotype of rs363371 was associated with a protective effect in male Chinese of developing SCZ. In future studies, more SNPs should be included and more risk factors should be involved in a much bigger sample size study recruiting patients from different ethnicities.
