Abstract

Corynebacterium jeikeium, a resident of human skin, is often associated with multidrug resistant nosocomial infections in immunodepressed patients. C. jeikeium K411 belongs to mycolic acid-containing actinomycetes, the mycolata and contains a channel-forming protein as judged from reconstitution experiments with artificial lipid bilayer experiments. The channel-forming protein was present in detergent treated cell walls and in extracts of whole cells using organic solvents. A gene coding for a 40 amino acid long polypeptide possibly responsible for the pore-forming activity was identified in the known genome of C. jeikeium by its similar chromosomal localization to known porH and porA genes of other Corynebacterium strains. The gene jk0268 was expressed in a porin deficient Corynebacterium glutamicum strain. For purification temporarily histidine-tailed or with a GST-tag at the N-terminus, the homogeneous protein caused channel-forming activity with an average conductance of 0.25 nS in 1M KCl identical to the channels formed by the detergent extracts. Zero-current membrane potential measurements of the voltage dependent channel implied selectivity for anions. This preference is according to single-channel analysis caused by some excess of cationic charges located in the channel lumen formed by oligomeric alpha-helical wheels. The channel has a suggested diameter of 1.4 nm as judged from the permeability of different sized hydrated anions using the Renkin correction factor. Surprisingly, the genome of C. jeikeium contained only one gene coding for a cell wall channel of the PorA/PorH type found in other Corynebacterium species. The possible evolutionary relationship between the heterooligomeric channels formed by certain Corynebacterium species and the homooligomeric pore of C. jeikeium is discussed.

Introduction

Members of the genus Corynebacterium are of considerable interest because some are potent producers of glutamate, lysine and other amino acids through fermentation processes on an industrial scale. Prominent examples of amino acid producers are Corynebacterium glutamicum or Corynebacterium callunae [1–6]. These bacteria belong to the family Corynebacteriaceae that is a distinctive suprageneric actinomycete taxon, the mycolata, which also includes mycobacteria, nocardiae, rhodococci and closely related genera. The mycolata share with the genus Corynebacterium the property of having an unusual cell envelope composition and architecture [7]. The mycolata have a thick peptidoglycan layer, covered by lipids as a permeability barrier on the surface of the Corynebacteria (22–38 carbon atoms) [12–16]. This means that the cell wall of the mycolata forms a permeability barrier and probably has the same function as the outer membrane of gram-negative bacteria. These membranes contain channel-forming proteins for the passage of hydrophilic solutes [17–19]. Similarly, channels are present in the mycolic acid layer of the mycobacterial cell wall and the cell walls of a variety of Corynebacteria, such as C. glutamicum, Corynebacterium efficiens, C. callunae, and Corynebacterium diphtheriae [20–25]. In all these cases it seems conceivable that PorA and PorH form heterooligomers responsible for the cation-selective major cell wall channel besides a smaller anion-selective channel [26,27]. Cell wall channels define the mycolic acid layer as a permeability barrier on the surface of the Corynebacteria similar as has been found in recent years by the investigation of cell wall channels in different members of the mycolata [24,28–32].

Corynebicarya (22–38 carbon atoms) [33], well known as the cause of diphtheria which is an acute, communicable respiratory disease. Other possible pathogens are only Corynebac-
Cell Wall Porin of Corynebacterium jeikeium

The bacterium may be multidrug-resistant and needs vancomycin for its treatment. Today the knowledge on the complete genome sequence of C. jeikeium K411, a clinical isolate originally recovered from the axilla of a bone marrow transplant patient, provides the basis for an in-depth understanding of the physiology of this medically important bacterium [39]. The chromosome of C. jeikeium K411 has a size of 2.46 Mbp and comprises 2104 predicted coding regions, of which 68 most likely represent pseudogenes. The chromosomal architecture of C. jeikeium K411 revealed a moderate number of genomic rearrangements when compared to other sequenced corynebacterial genomes [39]. These structural differences of the chromosome have been attributed very recently to the phylogenetic position of C. jeikeium within the taxonomic tree of the genus Corynebacterium [40]. Annotation of the genomic data revealed that the lipophilic phenotype of C. jeikeium is caused by the absence of a gene coding for a fatty acid synthase and linked to pathogenicity, and that events of horizontal gene transfer are responsible for multidrug resistance [39]. The annotated genome sequence can be regarded as starting point for comprehensive post-genomic studies at the transcriptomic and proteomic levels [41,42], but also for the detailed functional analysis of predicted coding regions, for instance the putative porin gene locus of C. jeikeium K411.

In this study, we extended the search for cell wall channels to the C. jeikeium strain K411 that is a clinical isolate with a known genome [39]. Using lipid bilayer experiments we could demonstrate that the extracts of whole cell wall channel and its flanking regions taken from the genome of C. jeikeium K411, a clinical isolate originally recovered from the axilla of a bone marrow transplant patient, provides the basis for an in-depth understanding of the physiology of this medically important bacterium [39]. The chromosome of C. jeikeium K411 has a size of 2.46 Mbp and comprises 2104 predicted coding regions, of which 68 most likely represent pseudogenes. The chromosomal architecture of C. jeikeium K411 revealed a moderate number of genomic rearrangements when compared to other sequenced corynebacterial genomes [39]. These structural differences of the chromosome have been attributed very recently to the phylogenetic position of C. jeikeium within the taxonomic tree of the genus Corynebacterium [40]. Annotation of the genomic data revealed that the lipophilic phenotype of C. jeikeium is caused by the absence of a gene coding for a fatty acid synthase and linked to pathogenicity, and that events of horizontal gene transfer are responsible for multidrug resistance [39]. The annotated genome sequence can be regarded as starting point for comprehensive post-genomic studies at the transcriptomic and proteomic levels [41,42], but also for the detailed functional analysis of predicted coding regions, for instance the putative porin gene locus of C. jeikeium K411.

In this study, we extended the search for cell wall channels to the C. jeikeium strain K411 that is a clinical isolate with a known genome [39]. Using lipid bilayer experiments we could demonstrate that the extracts of whole C. jeikeium cells contain a protein that forms wide and water-filled channels similar to the porins found in gram-negative bacteria and in other Corynebacteria [17,20,43]. The channel-forming protein, named PorACj, was identified within the accessible genome of C. jeikeium K411 [39] by using its homology to PorA of most Corynebacteria, PorACj was expressed in a PorA/PorH-deficient strain of C. glutamicum ATCC13032 [20,44] and purified to homogeneity. The protein is active as a homooligomer in contrast to PorA/PorH of most Corynebacteria, which form heterooligomeric channels [27]. We present in this study the characterization of the first homooligomeric channel-forming protein of the PorA type of a strain within the genus Corynebacterium, which is formed in contrast to other cell wall channels from the mycolata by alpha-helical stretches. A phylogenetic tree suggests that PorACj could be the ancestor of all known PorA/H proteins from Corynebacterium strains.

### Experimental Procedures

#### Bacterial Strains and Growth Conditions

The Corynebacterium strains C. glutamicum ATCC13032 and C. jeikeium K411 (obtained from the National Collection of Type Cultures, NCTC, London, UK) were grown in 1000 ml baffled Erlenmeyer flasks containing 250 ml of brain-heart infusion (BHI) media (Becton) and 250 ml Erlenmeyer flasks containing 25 ml BYT medium [45]. Former cultures were stirred on a rotary shaker at 140 rpm and 30°C, latter at 280 rpm and 37°C. *Escherichia coli* NEB5α (New England Biolabs), used for cloning, was grown under standard conditions in Luria broth (LB). If required agar plates and liquid media were supplemented with 20 and 40 μg/ml chloramphenicol, respectively.

### Cloning of jk0268

The gene jk0268 and its putative ribosome binding site was PCR amplified from genomic C. jeikeium DNA. It was isolated in a 50 μl reaction volume containing 1 × Taq buffer, 0.2 mM dNTPs, 5 mM MgCl2, 1 U Taq DNA polymerase (Fermentas) and 0.4 μM primers FP JK0268XbaI and RP JK0268EcoRI (Table 1). Used PCR conditions were: initial denaturing at 95°C for 5 minutes, 30 cycles at 95°C for 1 minute, 45°C for 1 minutes, 72°C for 1 minute and a final extension at 72°C for 10 minutes. A PCR product of ~ 200 bp was cut out after agarose gel size separation, ligated into TOPo2.1 vector (Invitrogen) and heat-shock transformed into *E. coli* NEB5α competent cells according to the instructions of the manufacturers. One plasmid containing the amplification was EcoRI and XbaI (Fermentas) digested and the 200 bp fragment was ligated in the backbone of EcoRI and XbaI linearized vector pXMJ19 [46] eventually resulting in the expression plasmid pXJK0268.

The sequences of the primers were derived from the prospective gene jk0268 of the cell wall channel and its flanking regions taken from the genome of C. jeikeium K411 [39]. Primer binding positions in the chromosome of the accessible genome of C. jeikeium K411 (reference sequence NC_007164) are provided.

Construction of a C-terminal His\textsubscript{8}-tag

For immobilized metal ion affinity purification (IMAC) the vector pXMJ19 was upgraded by introduction of a DNA cassette coding a C-terminal factor Xa (I-E-G-R) linked octa-histidine tag. Therefore, single-stranded oligonucleotides FP KpnIXa8HisEcoRI and RP KpnIXa8HisEcoRI were first 5\textsuperscript{9} phosphorylated, then annealed by a temperature gradient step to provide double-stranded DNA with KpnI and EcoRI overhangs and finally ligated in KpnI and EcoRI cut pXMJ19 vector (T4 DNA ligase, Fermentas). The resulted plasmid was designated pXHis. To apply the C-terminal tag of plasmid pXHis to \textit{jk0268} the native stop codon was mutated by PCR amplification. Using PCR

Figure 1. Study of pore-forming capacity of detergent extracts of \textit{C. jeikeium}. (A) Single-channel recording of a PC/n-decane membrane in the presence of the detergent extract of whole \textit{C. jeikeium} K411 cells. The aqueous phase contained 1 M KCl, pH 6 and 50 ng/ml protein extract. The applied membrane potential was 20 mV, T = 20°C. (B) Histogram of the probability P(G) for the occurrence of a given conductivity unit observed with membranes formed of 1% PC dissolved in n-decane. It was calculated by dividing the number of fluctuations with a given conductance rise by the total number of conductance fluctuations in the presence of detergent extracts of whole \textit{C. jeikeium} K411 cells. Two frequent conductive units were observed for 307 single events taken from 13 individual membranes. The average conductance of the steps corresponding to the left-side maximum was 1.25 nS and that of the right-side maximum was 2.5 nS. The aqueous phase contained 1 M KCl, pH 6 and 50 ng/ml protein extract, the applied membrane potential was 20 mV, T = 20°C.

Figure 2. Analysis of the accessible genomes from \textit{C. glutamicum}, \textit{C. efficiens}, \textit{C. diphtheriae} and \textit{C. jeikeium}. The homologous genes of the chaperonin GroEL2 and a poly phosphate kinase PPK2 enclose a presumed conserved porin domain. The operon covering the genes CgporH and CgporA whose proteins build the bicomponental main cell wall channel of \textit{C. glutamicum} is inferred to exist in all strains except for \textit{C. jeikeium}. Possible terminator sequences of mRNA transcripts were predicted with TranstermHP (indicated by hairpins [62]; or were identified manually (marked by asterisk).

doi:10.1371/journal.pone.0075651.g002
conditions mentioned before, primers FP pXMJ19Seq, RP JK0268KpnI and template pXJK0268 (pXMJ19 equipped with jk0268) provided a 250 bp fragment. This fragment as well as plasmid pXHis were XbaI and KpnI digested, over night ligated (16°C) and named pXJK0268His.

Expression of Recombinant PorACj-His8

Transformation of C. glutamicum ΔAH with pXJK0268His was performed by electroporation using a slightly modified standard electro-transformation method [47]. Heterologous expression of the protein was induced by addition of 1 mM IPTG (isopropyl-beta-D-thiogalactopyranoside) to a liquid culture at the mid-exponential growth phase.

Construction of an N-terminal GST-tag

Besides the C-terminal octa-histidine tag we introduced also an N-terminal GST-tag for the expression of PorACj in E. coli. For this a pGEX-2T expression vector (Amersham Biosciences, GE Healthcare, UK) was used. Due to the N-terminal fusion, the first methionine was removed and an additional transcription terminator was added to the jk0268 gene to cleave the fusion proteins partner. Sequence

Figure 4. Analysis of PorACj purification. (A) Western blot analysis illustrating IMAC purification of his-tagged PorACj protein. The protein was expressed in C. glutamicum ATCC13032 ΔporHΔporA and purified by Ni\(^{2+}\) affinity from the supernatant of detergent extracted whole cells. CMDIE represents chloroform-methanol treated cells in which the crude protein content was concentrated around 8 fold by diethyl-ether precipitation of pXJK0268His transfected (+) or non-transfected (−) C. glutamicum ΔporHΔporA cells. Subsequent to tricine (12%)-SDS-PAGE the gel was blotted on a nitrocellulose membrane and PorACj-His was visualized by Anti-His antibodies and a chemiluminescent reaction. All samples were boiled for 5 minutes in Redmix before loading. (B) Silver stained tricine (16.5%)-SDS-PAGE of Ni\(^{2+}\)-purified and factor Xa digested PorACj-His protein. Lanes: 1, 3 units of protease Xa (control); 2, 10 μl of three pooled Ni-NTA elution containing PorACj-His; 3, 10 μl of protease Xa treated and purified PorACj protein (for details see text). The dot blot immunoassay pictures underneath lanes 2 and 3 show cleavage of the histidine tail using anti-his antibody of 5 μl of the corresponding protein samples. Before loading all samples were boiled for 5 minutes in Redmix.

doi:10.1371/journal.pone.0075651.g005
analysis was done via double strand DNA sequencing into pCR2.1 vector (Eurofins MWG Operon, Germany). One pCR2.1-jk0268 plasmid containing the amplified modified DNA fragment was EcoRI and BamHI (NEB) digested and the 200 bp fragment was ligated in the backbone of EcoRI and BamHI linearised vector eventually resulting in the expression plasmid pGEX-2TJK0268. Subsequently, site-directed mutagenesis was utilized in pGEX-2T expression vector prior to usage, to convert R927 of the plasmid to G in the thrombin cleavage sequence (LVPR|GS CTG GTT CCG CGT GGATCC) to avoid any other cleavage site for Factor Xa protease.

The sequence of all expression vectors were verified by sequencing (Seqlab, Göttingen Germany) prior to transformation of the plasmids into competent porin deficient C. glutamicum ATCC 13032 ΔAHH or porin deficient BL21 DE3 Omp8 E. coli strains.

**Isolation of Cell Wall Proteins**

Cell wall-associated proteins were isolated by methods described in details previously [28,30]. A liquid culture of grown cells was centrifuged (6,000 rpm, 15 minutes, 4°C in Heraeus Minifuge RF centrifuge). The cell pellet was washed twice with 10% culture volume (10 mM Tris, pH8) before cell wall proteins were extracted either by shaking the cells in detergent solution or in a 1:2 (v/v) mixture of the organic solvents chloroform and methanol. For both extraction methods one part cells (0.3 g wet weight bacterial pellet) was resuspended in five parts detergent solution (1.5 ml 1% LDAO (lauryldimethylamine-oxide), 10 mM Tris, pH8) or organic solvent (1.5 ml chloroform/methanol). After 3 hours agitation at RT cells were sedimented in a table top centrifuge (10 minutes, 4°C, 10,000 rpm) and the pellet was discarded. The detergent supernatant was immediately applied to IMAC purification. The chloroform-methanol mixture had first to be precipitated with 9 times the volume of ice-cold diethyl ether (16 h, 220°C) before the obtained pellet was either resolved in detergent solution (1% LDAO, 10 mM Tris, pH8) or in loading buffer for gel electrophoresis [28].

**IMAC Purification**

Histidine-tailed C. jeikeium protein was purified to homogeneity by utilization of immobilized metal ion affinity chromatography (IMAC). From detergent treated cells 5 ml of the 1% LDAO supernatant were loaded on Ni-NTA spin columns (Qiagen) equilibrated with buffer 1 (20 mM Tris, 50 mM NaCl, 0.4% LDAO, pH8). After ten washing steps using each 650 ml of buffer 2 (= buffer 1 with 10 mM imidazol) bound protein was eluted from the column with 200 ml buffer 3 (= buffer 1 with 300 mM imidazol).

**Expression of Recombinant GST-jk0268**

The plasmid including desired gene was sequenced afterward and transformed into the porin deficient BL21 DE3 Omp8 E. coli. Cells were grown at 37°C in LB medium and induced by 1 mM IPTG. The culture media incubated over night at 26°C after induction. Subsequently, cells were harvested by centrifugation at 4,000 xg for 20 minutes at 4°C and were resuspended in PBS.
phosphate buffered saline (pH 7.4) then lysed with a high-pressure-homogenizer (2 x 1500 bar). Unbroken cells removed by centrifugation, supernatant used for purification.

GST-PorACj Fusion Protein Purification

Purification of GST-PorACj was performed using glutathione sepharose 4B medium, (following batch protocol GST Gene Fusion System Handbook, GE Healthcare). After 5 times washing with buffer A (0.5% Genapol, 100 mM NaCl, 50 mM Tris-HCl, 1 mM CaCl2, 2.5 mM DTT, pH 7.4) to remove non-bound sample components, the purified GST-fusion protein was eluted by addition of buffer A supplemented with 10 mM Glutathione, pH 8. The protein sample was concentrated using amicon ultra 3 kDa [Millipore] to a concentration of 3 mg/ml GST-PorACj determined using OD280. Uses 30 ml of sample highly specific detect only GST fusion protein. Western blotting was carried out using anti-GST antibody. (Data not shown).

Protease Xa Cleavage of PorACj-His8

Subsequent to IMAC purification the sample contained high imidazol concentrations which strongly inhibit protease Xa (Qiagen) activity. Removal of imidazol was performed by dialysing the sample over night against cleavage buffer (20 mM Tris, 50 mM NaCl, 1 mM CaCl2, 0.4% LDAO, pH6.5) using a cellulose membrane with a MWCO of 2 kDa (Spectra/Por 6, Carl Roth, Germany). For cleavage of the poly-histidine-tag 4 units protease Xa (Qiagen) were added to the sample (37 °C, over night). The enzyme was removed with the factor Xa removal Kit according Qiagen instructions while the cleaved JK0268 (PorACj) protein was separated from uncleaved PorACj-His8 by a second passage through a Ni-NTA filter.

Protease Xa Cleavage of PorACj-GST

The purified GST-PorACj contained 10 mM of glutathione. PorACj was dialysed for 36 h at 4 °C with constant stirring in glutathione and DTT free buffer (100 mM NaCl, 50 mM Tris,
Table 4. Radii of the anions and relative permeability of PorACj from C. jeikeium in different salt solutions.

| Anion | Radii of the hydrated anions a [nm] | Limited molar conductivity \( \lambda_i \) [mS/M] | Permeability relative to 0.1 M KBr |

| HCOO\(^-\) | 1.50                              | 54.59                             | 0.38              | 0.46              |
| CH\(_3\)COO\(^-\) | 2.00                              | 40.90                             | 0.29              | 0.34              |

The data for the limiting conductivities of the different ions were taken from ref. [66]. The radii of the hydrated anions were calculated using the Stokes equation [67]. The single channel conductance of PorACj for the different salts at 0.1 M was taken from Table 3. The relative permeability of the single anions was calculated by dividing the single-channel conductance of the individual anion by that of 0.1 M KBr. The relative permeability for 0.1 M KBr was set to unity.

doi:10.1371/journal.pone.0075651.t004

0.5% Genapol, 1 mM CaCl\(_2\), pH 8.0 at room temperature). Then 2 units FXa protease (NEB) was added for 16 h at 22\(^\circ\)C to the protein solution. No DTT was added to the dialysis buffer, because of its absorption for CD measurement. The sample was loaded again onto glutathione-agarose 4B medium and the flow through was collected. A concentration of 0.65 mg/ml pure PorACj was determined using OD\(_{280}\).

Protein Electrophoresis and Immunoblotting

Protein samples were size separated subsequent to a denaturation step (5 minutes, 95\(^\circ\)C) with Tris-Tricine 12% or 16.5% polyacrylamide gels [48]. After electrophoresis gels were either stained with Coomassie Brilliant Blue G-250, or by silver stain [49] or electroblotted [50]. In the latter case, proteins were transferred to a 0.1 \(\mu\)m nitrocellulose membrane (Protran, BA79, Whatman). The blotting was performed for 4–5 minutes in a wet tank blot system (Biorad) with Towbin buffer (25 mM Tris, 192 mM glycine, 20% methanol) at 350 mA current. Unspecific binding sites on the membrane were blocked with 5% skimmed milk in TBS-T buffer (20 mM Tris, 0.01 M NaCl, 0.1% Tween, pH 7.5) before probing with the first 1:5000 diluted monoclonal mouse Anti-his antibody (Amersham Biosciences, UK). Subsequent to multiple TBS-T washing steps the second peroxidase-conjugated Anti-Mouse antibodies (DAKO, Denmark) were added at the same dilution. Attending to the manufacturer’s instructions use of the ECL Western blotting detection system (GE Healthcare, UK) resulted in light emission recorded on autoradiography films (Hyperfilm\(^\text{TM}\)MP, GE Healthcare, UK). Dot blot immunodetection was carried out identically without prior SDS-PAGE. Exposure times varied between 10 seconds to 5 minutes as required by the sample.

Test for Susceptibility to Antibiotics

Sterilized Whatman filter disks with 5 mm diameter were used for qualitative tests. Overnight cultures in the suitable medium were diluted 1:1,000; then 1 ml of each culture containing approximately 10\(^{8}\) cells/ml was spread onto BHI agar medium (Difco) containing 1 mM IPTG. Five-microliter portions of the diluted 1:1,000 stock solutions of the different antibiotics were deposited to each disk. The diameters of the growth inhibition zones were measured after 16 and 24 h. The concentrations of the antibiotics in the growth inhibition zone experiments were: ampicillin, 100 \(\mu\)g/ml; penicillin G, 100 \(\mu\)g/ml; carbenicillin, 100 \(\mu\)g/ml; cefazolin 100 \(\mu\)g/ml; ertapenem, 20 \(\mu\)g/ml; imipenem, 10 \(\mu\)g/ml; gentamicin, 25 \(\mu\)g/ml; tetracycline 25 \(\mu\)g/ml; Besides the qualitative evaluation of the antibiotic susceptibility also the minimum concentration (MIC) of antimicrobial agents was measured, which inhibits the growth of the different C. glutamicum strains used in this study. The stock concentration of the antibiotics in these experiments were the same as above for the growth inhibition zones.

CD Measurements

CD measurements were performed on a Jasco J-810 circular dichroism spectropolarimeter using 0.1 cm light pathway cells at room temperature while flushing the cuvette chamber with nitrogen gas. Spectra were recorded from 190–260 nm with a resolution of 1 nm and an acquisition time of 200 nm/minutes.

Figure 10. Fit of the single-channel conductance data of PorACj by using the Renkin correction factor times the aqueous diffusion coefficients of the different anions [67]. The product of both numbers was normalized to 1 for \(a = 1.05 \text{ nm} (\text{Br}^-)\). Single-channel conductance was normalized to the one of 0.1 M KBr and plotted versus the hydrated ion radii taken from Table 3. The single-channel conductance correspond to \(\text{Br}^-\), \(\text{Cl}^-\), \(\text{NO}_3^-\), \(\text{ClO}_3^-\), \(\text{F}^-\), \(\text{HCOO}^-\) and \(\text{CH}_3\text{COO}^-\) which were all used for the pore diameter estimation. The fit (solid lines) is shown for \(r = 0.5 \text{ nm}\) (lower line) and \(r = 0.9 \text{ nm}\) (upper line). The best fit was achieved with \(r = 0.7 \text{ nm}\) (diameter = 1.4 nm) corresponding to the broken line.

Ten scans were taken for each sample, and the average of these scans was smoothed and stored for further analysis. Blanks of the respective protein-free sample were recorded under the same conditions and subtracted from the protein spectrum before further analysis. Analysis of the CD spectra was performed by expressing the spectra as linear combinations of 4 reference spectra (alpha-helix, beta-sheet, beta-turns and random-coil) as described elsewhere by using public domain programs [51].

**Black Lipid Bilayer Membranes**

The methods used for the lipid bilayer experiments have been previously described in detail [52]. In the experimental setup two compartments of a Teflon cell filled with electrolyte solution are connected by a small circular hole with an area of about 0.2 mm². The black lipid bilayer membrane was made by painting a 1% (w/v) diphytanoyl phosphatidylcholine (PC)/n-decane solution (Avanti Polar Lipids, Alabaster, USA) across the hole. Ag/AgCl electrodes were used connected in series to a voltage source and a homemade current-to-voltage converter for the electrical measurements. The bandwidth of the instrument was set to 100–300 Hz dependent on the magnitude of the output signal. The amplified signal was monitored with a digital oscilloscope and recorded with a strip chart recorder. All salts were obtained from Merck (Germany) or Sigma-Aldrich (Germany) at analytical grade. The aqueous salt solutions were unbuffered and, if not explicit mentioned, had a pH of around 6. The temperature during all experiments was maintained at 20°C. The zero-current membrane potential measurements were performed as it has been described earlier [53] by establishing a 5-fold salt gradient across membranes containing 10–1000 cell wall channels. Zero-current potentials were measured using a high impedance electrometer (Keithley 617).

Figure 11. Analysis of PorACj secondary structure. (A) The panel shows the hydrophobicity indices of the individual amino acids of PorACj according to ref [80]. (B) The secondary structure of PorACj was predicted using a consensus method [83] at the Pole Bioinformatique Lyonnaise network (http://npsa-pbil.ibcp.fr/cgi-bin/npsa_automat.pl?page = /NPSA/npsa_seccons.html); the protein was suggested to form β-helices. Amino acid residues arranged on basis of heptameric repeats (a–g) showing distinct separation in a hydrophobic domain supposable surrounded by lipid molecules (dark grey) while the hydrophilic domain (light grey) is suggested to represent the component orientated to the water-filled lumen in the presumed oligomeric PorACj.

doi:10.1371/journal.pone.0075651.g011
Cell Wall Porin of Corynebacterium jeikeium

Results

Cell Wall Proteins Effect the Conductance of Lipid Bilayer Membranes

Cells of an overnight grown C. jeikeium culture were extracted with 1% LDAO. A few µl of the crude cell wall extract were tested in the lipid bilayer assay for pore-forming activity (see Figure 1A). Independently, if added to one or both sides of the lipid membranes two discrete conductance steps with 1.25 and 2.5 nS were observed at 20 mV applied membrane potential in 1 M KCl solution (see Figure 1B). Furthermore, the conductance increase caused by the detergent extract was a function of time after the addition of the protein to membranes in the black state. Within about 20 to 30 minutes the membrane conductance increased by several orders of magnitude above that of membranes without the extracts (from about 0.05 µS/cm² to 150 µS/cm²). Control experiments with LDAO alone at the same concentration as in the experiments with extracts demonstrated that the membrane activity was caused by the presence of the extracts and not by the detergent. This result suggested that the channel-forming activity was an intrinsic property of the detergent extracts of whole C. jeikeium cells.

Identification of the Gene Coding for the Cell Wall Channel of C. jeikeium K411

The extracts from whole C. jeikeium cells contained too many bands in tricine containing SDS-PAGE that it was impossible to relate one single band to the channel-forming activity although it showed a strong band in the low molecular mass region. Excision of the low molecular mass bands from preparative SDS-PAGE suggested that they contained the channel-forming proteins (data not shown). We looked for an alternative method to identify the channel-forming protein. Previously we could identify PorA of C. diphtheriae based on its homology with PorA of C. glutamicum and other Corynebacterium [20,30,44]. Therefore, we performed a similar approach here. A NCBI BLAST-translation tool search [54,55] using porA of C. glutamicum in the known genome of C. jeikeium K411 [39] did not lead to a clear indication for a homologous gene. However, search within the genome suggested that it contained an open reading frame (ORF) between the genes coding for GroEL2 (jk0267; [56]) and a hypothetical protein (polynphosphate kinase (PKK2), jk0269) that could code for a low molecular mass cell wall protein similar to PorA (see Figure 2). This means that an ORF (named jk0268) is localized within a region homologous to that of the C. glutamicum genome containing porA and porH [27]. Primers were designed to clone the whole region between the two genes jk0267 (GROEL2) and jk0269 (polynphosphate kinase) using DNA of C. jeikeium as a template (see Table 1). The PCR-product was cloned into the TOPO 2.1 vector and was sequenced. It contained jk0268 that could code for a PorA-like protein.

The involvement of JK0268 (named in the following PorACj for PorA of C. jeikeium) in the observed channel formation of C. jeikeium extracts was examined by expressing the corresponding gene jk0268 in a C. glutamicum mutant deficient of its main cell wall channel [44]. Whereas in terms of identical treatment cell wall samples of the C. glutamicum mutant did not show any channels reconstituted in a planar bilayer membrane, samples of pXJK0268 transformed and IPTG induced mutant cells caused well-defined step-wise channel events that were very similar to those shown in Figure 1 (data not shown). These channels were identical to those observed after addition of the C. jeikeium extracts to lipid bilayer membranes, which means that two maxima of 1.25 and 2.5 nS were observed in 1 M KCl (see Figure 1). This result suggested that PorACj is the cell wall channel of C. jeikeium.

Figure 12. Analysis of the putative quaternary structure of PorACj. (A) Model of the octameric form of the PorACj channel in a lipid bilayer membrane as derived from the experimental measurements. While the secondary structure is colored in purple, the individual amino-acid side chains are depicted as ball chains and colored according to their electrophysiological nature, i.e., neutral/hydrophobic in grey, polar in green, and charged in red (negative) and blue (positive), respectively. The surrounding bilayer is drawn as a grey surface. (B) Side view of the model of the octameric PorACj channel. After a few tenth of nanoseconds of unbiased molecular dynamics simulations, the helices kink in the central region - forming an hourglass shape - where several short side chains of the amino acids are located. The blue ball-stick side chains represent the lysines in the lower region, which are presumably responsible for the ion selectivity of PorACj and which form some kind of constriction zone.
Comparison of PorACj with PorA and PorH of Other Corynebacteria

Figure 3 shows a comparison of the sequences of the major cell wall proteins PorA and PorH of different Corynebacteriae with that of PorACj derived with Clustal W Protein sequences multiple alignments from Pole Bioinformatique Lyonnaise Network Protein Sequence Analysis (http://npsa-pbil.ibcp.fr). The multiple alignments were controlled with AliBee (www.genebee.msu.su). The protein has similar to PorA and PorH known to date only the inducer methionine but no presequence similar to PorA and PorH of C. glutamicum [21,23], which means that the proteins are exported to the cell wall by a not yet identified mechanism. Similar is also the length of PorACj (40 amino acids) as compared to that of the different PorA (on average 43 amino acids) and PorH (57 amino acids) proteins. Otherwise, the homology is very poor in particular to PorH because only a limited number of amino acids are preserved (see Figure 3). Nevertheless, it is clear that the sequences of the different proteins are related, which means that they are presumably descendents of a common ancestral protein (see Discussion).

Antibiotic Resistance

The antibiotic susceptibility of C. glutamicum ΔHA cells expressing PorACj was examined qualitatively by using the filter disk method and measuring the diameter of growth inhibition zones (see Table 2). The latter method was performed with C. glutamicum ATCC13032 wildtype as control, C. glutamicum ATCC13032 ΔHA and C. glutamicum ΔHA pXHis PorACj. Whereas a considerable decrease of the antibiotic susceptibility was observed between wildtype and the ΔHA mutant similar to that observed previously [20], expression of PorACj had an only minor influence on the antibiotic susceptibility of this mutant strain showed that it was the same for antibiotics such as penicilline G, carbenicillin, cefazidime, ceftepam and imipenem. Only for ampicillin, gentamicin and tetracycline the C. glutamicum ΔHA pXHis PorACj.
**glutamicum ΔHA** pXHis PorACj strain was slightly more susceptible indicating some minor increase of cell wall permeability in the presence of PorACj.

To determine the minimal concentration of antimicrobial agents, which inhibits the growth of the different *C. glutamicum* strains used in this study, we performed dilution susceptibility tests. This was achieved by dilution of antimicrobial agents in broth media. Antimicrobials were tested in series of two-fold dilutions. The minimum inhibitory concentration (MIC) was measured for *C. glutamicum* ΔHA as a control and *C. glutamicum* ΔHA pXHis PorACj. The results are summarized in Table 2. In general, reduction of antibiotic transport in bacteria using several classes of antibiotics such as β-lactams, aminoglycosides or fluoroquinolones, is mainly caused by changes of membrane permeability [19,57]. Loss of porins or expression of modified porin structure can cause low uptake of fluoroquinolones and β-lactams. The results of our study demonstrated that *C. glutamicum* ΔHA was still susceptible to all antibiotics. There did also not exist significant differences between *C. glutamicum* ΔHA and *C. glutamicum* ΔHA pXHis PorACj for all antibiotics except for tetracycline, gentamicine and penicillin G. This suggests that *C. glutamicum* ΔHA may have some leakage in the cell wall caused by deletion of its major cell wall channels and therefore did not provide a proper control for the change of cell wall permeability for uptake of antibiotics when PorACj is expressed.

**Heterologous Expression and Purification of the C-terminal His<sub>8</sub>-tagged and the N-terminal GST-tagged Channel-forming Protein PorACj**

Cell wall preparations taken either from *C. jeikeium* or *C. glutamicum* expressing PorACj indicated a significant contribution of this protein to the observed channels. For purification of the protein we used a PCR based mutagenesis approach to introduce a DNA sequence coding a protease Xa cleavable, 8 histidine residues comprising protein tail which was added to the C-terminus of the wild-type gene. The constructed DNA cassette, accounting for the *C. glutamicum* codon usage frequencies [58], was introduced in the pXMJ19 expression vector and the stop codon (TAG) of *jkl0268* was substituted (GGT) to fuse the peptide tail.

From IPTG-induced and detergent-extracted *C. glutamicum* cells expressing PorACj it was not possible to directly observe expression of neither the wild-type nor the modified *C. jeikeium* protein in SDS-PAGE. Only higher concentrated samples of chloroform/methanol precipitates combined with immunosassay using an anti-His antibody revealed expression of a small-sized protein as revealed by Western blots with detergent extracts of induced and not induced cells (see Figure 4A). Its molecular mass matched well with the calculated MW of PorACj-His (6.2 kDa). In a next step, the protein was purified from detergent extracts by Ni<sup>2+</sup> affinity chromatography (see Figure 4B). The pure and still histidine-tagged protein was able to form channels after trace amounts were added to the aqueous phase in the lipid bilayer setup (not studied in detail). To approach the situation of the native protein the His-tag was cleaved by protease Xa and the truncated PorACj protein (containing the C-terminal linker residues G-T-I-E-G-R) was again purified to homogeneity (Figure 4B). Similar results were obtained from lipid bilayer experiments with PorACj as obtained from expression in *E. coli* with the exception that uncleaved GST-PorACj did not form channels (data not shown).

The yield of the expression of the N-terminal GST-PorACj was at least ten times higher than described above for the His<sub>8</sub>-tagged protein. Purification of the GST-tagged PorACj was performed using glutathione Sepharose 4B medium. The protein was eluted with an elution buffer containing 10 mM glutathione. The protein sample was concentrated to a concentration of 3 mg/ml pure GST-PorACj protein as judged by SDS-PAGE and Western blotting (Data not shown). The GST-tag of the pure protein was removed by cleavage with FXa protease followed by treatment with glutathione Sepharose 4B medium to remove trace amounts of uncleaved GST-PorACj. The final concentration of pure PorACj was 0.65 mg/ml as judged by measurements at OD<sub>280</sub>. All further biophysical measurements were performed with pure PorACj obtained by cleavage of the His<sub>8</sub>-tag of PorA-His<sub>8</sub> or by cleavage of the GST-tag of GST-PorACj.

**Single-channel Analysis of PorACj**

Addition of small amounts of the purified PorACj (~10 ng/ml) to one or both sides of a black lipid membrane made of PC/n-decane resulted after a few minutes delay in observation of step-like conductance increases. These channels had the same size as described above for detergent-stabilized material from *C. jeikeium* and *C. glutamicum* pXJK0268. This means that most of the steps were directed upwards indicating that the channels were for long time in an open state under low voltage conditions (20 mV; see Figure 5A). Only few channels showed some flickering indicating transitions between open and closed states. The statistical analysis similar to that shown in Figure 1B indicated that most of the channels (more than 40% of all fluctuations) caused conductivity steps with 1.25 or 2.5 nS in 1 M KCl (20 nV applied membrane potential; see Figure 5B). This means that a major conductance step of about 1.25 nS we observed also channels with a higher single-channel conductance, in particular channels with a single-channel conductance of about 2.5 nS. It is possible that the two different channels represent two different arrangements of the PorACj monomers (see discussion). Interestingly, we found a 1:2 relationship for the two maxima within the histograms under all conditions used here, which were denoted as left-side and right-side maximum in the histograms. Single-channel experiments were also performed with salts containing ions other than K<sup>+</sup> and chloride. These experiments were done to get some insight in the biophysical properties of the cell wall porin of *C. jeikeium*.

The results summarized in Table 3 suggested that the channel may be moderately selective for anions. This conclusion could be derived from experiments in which KCl was replaced by LiCl or KCH<sub>3</sub>COO. The exchange of the mobile ions K<sup>+</sup> and Cl<sup>-</sup> by the less mobile ions Li<sup>+</sup> and acetate indicates that cations and anions have certain permeability through the channel of *C. jeikeium*, although the effect of anions on the single-channel conductance was more substantial. The permeability of the anions through the channels followed approximately their mobility sequence in the aqueous phase. This probably means that the channels formed by PorACj are wide and water-filled and have only a small field strength inside and no small selectivity filter (i.e. no binding site) as is suggested by the fact that large organic anions could also penetrate the channel (see Discussion).

Table 3 shows also the average single-channel conductance, G, as a function of the KCl concentration in the aqueous phase. The values for G always corresponded to those of the two maxima in the histograms, i.e. to the 1.25 and 2.5 nS peaks in the case of 1 M KCl. Measurements were performed down to 0.01 M KCl. In contrast to other cell wall channels of the mycolata [23,28,30,59], we observed a linear relationship between single-channel conductance and KCl-concentration, which would be expected for wide water-filled channels that do not contain point charges similar to those formed by gram-negative bacterial porins [17,43]. This means the cell wall channels of *C. jeikeium* are together with those of *C. diphtheriae* [44] the first ones without point charge effects on the
channel properties within the taxon Corynebacteriae (see also Discussion).

Selectivity of the Cell Wall Channel of C. jeikeium

Zero-current membrane potential measurements were performed to obtain further information on the structure of the C. jeikeium cell wall channel. The experiments were performed in the following way. After the incorporation of 100 to 1000 channels into the PC membranes bathed in 100 mM salt solution, the salt concentration on one side of the membranes was raised fivefold by addition of 500 mM salt solution. For KCl, KCH$_3$COO the more diluted side of the membrane (100 mM) always became negative, which indicated for all three salts preferential movement of the anions. The results indicate that the channel functions as a general diffusion pore for negative and cations in the aqueous phase, i.e. it is indeed water-filled.

The Cell Wall Channel of C. jeikeium is Voltage-dependent

In single-channel recordings, the cell wall porin exhibited some flickering at higher voltages, i.e. it showed rapid transitions between open and closed configurations. This could be caused by voltage-dependent closure of PorACj, which was studied in detail in multi-channel and single-channel experiments. In the first set of experimental conditions, PorACj was added in a concentration of 0.9 nM to one side of a black PC/n-decane membrane (the cis-side). After 30 minutes the conductance reached a stationary state. At this time, different positive and negative potentials were applied to the cis-side of the membrane. For negative and positive potentials at the cis-side of the membrane the current decreased in an exponential fashion (see Figure 6 for voltages between ±30 mV and ±60 mV). This result indicated symmetrical voltage-dependence of the cell wall channel. The addition of the protein to the trans-side of the membrane or to both sides of the membrane also resulted in a symmetric response to the applied voltage (data not shown).

In a second set of experiments, PorACj was added in a concentration of about 10 ng/ml to one side of a black PC/n-decane membrane. After the reconstitution of about 10 channels into the membrane we applied +40 mV to the cis-side of the membrane and followed the time course of the current for about 10 minutes as it is shown in Figure 7A. Because of the limited lifetime of the PorACj channel at higher voltages, the channels switched to substates. Figure 7B shows the distribution of the channel closures and the conductance as a function of the conductance. Two main peaks of conductance were observed. One had a conductance of 1 nS and the other one 2 nS in 1 M KCl. When we keep the onset of conductance with 1.25 and 2.5 nS under the same conditions in mind (see figures 1 and 5), then it is possible that the 1.25 nS channel closes with 1 nS, whereas the 2.5 nS channel closes with 2.0 nS.

The data of the multi-channel experiments similar to that shown in figure 6 were analyzed in the following way: the membrane conductance (G) as a function of voltage, V_m, was measured when the opening and closing of channels reached an equilibrium, i.e. after the exponential decay of the membrane current following the voltage step V_m. G was divided by the initial value of the conductance G_o, (which was a linear function of the voltage) obtained immediately after the onset of the voltage. The data of figure 8 correspond to the symmetric voltage-dependence of the cell wall porin (mean of four membranes) when the protein was added to the cis-side (closed squares). To study the voltage-dependence in more detail the data of Figure 8 were analyzed assuming a Boltzmann distribution between the number of open and closed channels, N_o and N_c, respectively [60]:

$$N_0/N_c = \exp \left( \frac{nF(V_m - V_0)}{RT} \right)$$  \hspace{1cm} (1)

F, R and T are standard symbols (Faraday constant, gas constant and absolute temperature, respectively), n is the number of charges moving through the entire transmembrane potential gradient for channel gating and V_m = V_o is the potential at which 50% of the total number of channels are in the closed configuration. The open-to-closed ratio of the channels, N_o/N_c, may be calculated from the data in Figure 8 according to

$$N_0/N_c = (G - G_{\text{min}})/(G_0 - G)$$  \hspace{1cm} (2)

G is in this equation the conductance at a given membrane potential V_m, G_o and G_{\text{min}} are the conductance at 10 mV (conductance of the open state) and at very high potentials, respectively. The data of Figure 8 could be fitted with combination of eqs. (1) and (2). The fit allowed the calculation of the number of gating charges n (number of charges involved in the gating process) and the midpoint potential V_o (potential at which the numbers of open and closed channels are identical). The midpoint potential for the addition of the protein to the cis-side was for applied positive voltages about +25 mV and for applied negative voltages about −24 mV. The gating charge was in both cases close to 2 (1.9 elementary charges).

Investigation of the Secondary Structure of PorACj by CD Measurements

Secondary structure predictions [http://npsa-phil.ibcp.fr/cgi-bin/npsa_automat.pl?page=/NPSA/npsa_seconns.html] suggested that the channel formed by PorACj contained alpha-helices in contrast to the known structure of gram-negative bacterial porins [17] and MspA of the gram-positive Mycobacterium smegmatis [61], which are formed by beta-strands. Therefore, we considered it as a good model for studies, in which the folding characteristics and the structure of this protein under different conditions were investigated. PorACj and PorACj-His$_8$ were solubilized in in solution containing 100 mM NaCl, 50 mM Tris-HCl and 1 mM CaCl$_2$, pH 8 supplemented with 0.5% Genapol. The concentrations were 69 μM for PorACj and 12 μM for PorACj-His$_8$, which was high enough to obtain a reasonable signal to noise ratio in the CD spectra. For both protein samples we found peaks in the CD-spectra around 208 nm and shoulders at about 220 nm (Figure 9A), which is typical for a high content of alpha-helical structures in proteins. This was confirmed by the fit procedure of the CD-spectra, which resulted in an estimate of about 80–100% alpha-helical structure, somewhat dependent on the type of public domain program used for the fit procedure. For control purpose, we performed CD-spectra with the same protein samples at the same concentrations to which urea was added in a concentration of 4 M. Figure 9B demonstrates that the spectra for both PorACj species changed completely. The peaks of the spectra are no
between 190 nm and 206 nm indicating that the spectra could be explained by random coil structure.

Discussion

The Genome of C. jeikeium Contains Only One Gene Coding for a PorA-like Cell Wall Channel

In this work, we extended our study of channel-forming proteins within the family of Corynebacteriaceae to the species C. jeikeium. Methodologies used previously for the isolation and characterization of cell wall-associated, channel-forming proteins showed that the supernatant of detergent extracted C. jeikeium cells also contained channel-forming units that form in the lipid bilayer assay channels with a conductance of 1.25 ± 2.5 nS in 1 M KCl (Figure 1). Preparative SDS-PAGE suggested that a small sized protein present in C. jeikeium was responsible for the pore-forming activity similar to that of PorH and PorA porins of C. glutamicum, C. callunae, C. efficiens and C. diphtheriae [21,22,28,44]. Therefore, the localizations of porH and porC genes within the chromosomes were compared with the homologous region of C. jeikeium. The results suggested that these genes are located in a conserved region flanked by genes coding a chaperonin (GroEL2) and a polyphosphate kinase (PPK2). Applied to C. jeikeium, the region between the genes jk0267 and jk0269 was astonishingly smaller than that of the other Corynebacteriae. It contained only one open reading frame (ORF), jk0268 containing 123 nucleotides and coding for a 40AS long polypeptide with a calculated MW of 4401 Da. The gene contains 6 bp upstream of the inducer methionine a putative ribosome-binding site (5′-AGGAG-3′). Furthermore, various predicted rho-independent terminator sequences suggested that the gene jk0268 similar to the situation in the genome of C. glutamicum transcribes autonomously of the surrounding genes. Substantiated downstream of jk0268 by a high-scored (100) stem-loop structure (5′-CCC CGGGCTTGGCGGGGG -3′) upstream structures are probably able to end GroEL2 mRNA transcription (score value 39–66) [62].

It is now clear that the major cell wall channels of most Corynebacteriae, i.e., those of C. glutamicum, C. callunae, C. efficiens and C. diphtheriae, are formed by oligomers of two small polypeptides, PorA and PorH [27]. However, this study demonstrates that in contrast to this the major wall channel of C. jeikeium is formed by an oligomer of a single PorA-like polypeptide. There are two clear findings supporting this. (i) There exists only a single gene (jk0268) between jk0267 (GroEL2) and jk0269 (PPK2), whereas in the same region within the genomes of the other Corynebacteriae two genes are localized that are transcribed together. (ii) We cloned jk0268 in expression plasmids. Its expression in a C. glutamicum mutant that lacked the genes coding for PorA and PorH resulted in the same channels observed from detergent [or organic solvent] extracts of C. jeikeium K411 cells. Similarly, PorACj expressed in E. coli resulted in the same channels as the recombinant protein expressed in C. glutamicum ΔAH. This result revealed that oligomers of a short 40 amino acids long polypeptide are sufficient to form channels in the cell wall of Corynebacteriae.

Analogous to the situation of PorH and PorA proteins of C. glutamicum, C. callunae, C. efficiens and C. diphtheriae the C. jeikeium PorACj polypeptide does not contain N- or C-terminal or twin-arginine sorting signals commonly used by gram-positive bacteria for Sec- or TAT-transport [63–66]. This means that PorACj uses the same, but still unknown transport mechanism for cell wall proteins of Corynebacteriae to overcome the cytoplasmic membrane to reach the cell wall. The single PorACj polypeptide monomers themselves are undoubtedly not large enough to form the observed channels. On the other hand, oligomerization was frequently observed in the field of porin research within mycolomycetes [28,31,44,61].

PorACj Forms Wide Water-filled Channels with No Indication for Point Charges

We observed two conductance values in the reconstitution experiments with PorACj in all salt solutions (see Table 3). The single channel conductance showed a relation of about 1:2 and reflected most likely two different channel configurations. A different number of monomers in a PorACj oligomer may cause the two configurations because the pore-forming unit may partially or completely dissociate in detergents or organic solvents during the isolation and purification process. Two configurations of channel closures were also observed in experiments where we studied the voltage dependence of PorACj. However, it is clear from the experiments that the channel did not close completely at higher voltages (see figure 7). This means presumably that the two maxima in the histograms do not reflect the reconstitution of one or two channels at once but reflect two conformers of PorACj.

The conductance of the channels formed by PorACj was a linear function of the bulk aqueous concentration (see Table 3). Similarly, the selectivity of the PorACj channels was dependent on the mobility of the ions in the aqueous phase. This means that the PorACj channels sort mainly according to the molecular mass of the solutes similar to the function of general diffusion pores in gram-negative bacteria [17]. This result is very surprising because up to date many cell wall channels within the taxon mycolata were identified that contained charges in or near the channel opening. The channel presented in this study is the second channel within the Corynebacteriae besides PorA/PorH of C. diphtheriae [44] that does not contain point charges. This means also that the single channel analysis does not allow estimation of the channel size on the basis of the existence of point net charges as was performed for cell wall channels of Mycobacteria, Nocardia and Corynebacteriae [25,28,31]. On the other hand, a rough estimate of the size of the PorACj channel could be provided from a fit of the single channel data for salts of different anions using the Renkin equation [67]. This was possible because the channel was anion selective under all conditions, which means that the single-channel conductance was mostly limited by the permeability of the anions through PorACj. Furthermore, the permeability of the anions moving through the channel followed approximately their mobility sequences in the aqueous phase (Br > Cl > NO3 > CO32 > F > HCOO > CH3COO). This means that the anions passing through the channel interior do not interact much with the channel. Table 4 contains the limiting molar conductivity adopted from ref. [68], the hydrated anion radii calculated according the Stokes equation [67] and the single-channel conductance of the C. jeikeium porin which was set to unity relative to the conductance in 0.1 KBr. The fit of the normalized single-channel conductance (mean of the left- and right-hand relative permeability) of PorACj with the Renkin correction factor (eqn. (2) of [67]) times the aqueous diffusion coefficient of the corresponding anion is shown in Figure 10. The best fit of the relative permeabilities was obtained with r = 0.7 nm (diameter 1.4 nm). Thus, the C. jeikeium porin is ranking into known channel diameters varying from 1.4 over 2.0 to 3.0 nm of different mycolata, such as Nocardia farcinica, Rhodococcus erythropolis and Mycobacterium smegmatis [30,31,61]. However, it was considerably smaller than that of the main PorA/PorH cell wall channel from C. glutamicum with 2.2 nm [28].
Putative Structure of the Channel Formed by PorACj

The comparison of the sequences of different PorA and PorH proteins with PorACj of C. jeikeium (Figure 3) demonstrated that the latter one is more comparable in size to the different PorA proteins. In addition, the alignments do not allow a distinctive allocation to PorA or PorH because each class affiliated members show with 13.6% (PorH) and 11.1% (PorA) a remarkable low degree of conserved residues as compared to PorACj. Nevertheless, there existed something like a structural homology between PorACj and the other two channel-forming proteins (PorA/H). Secondary structure predictions of all three proteins suggested that they contain heptameric repeat motive (abcdefg, see Figure 11A) indicating the existence of large β-helical structures with hydrophobic and hydrophilic residues localized on different sides of the helices. Figure 11B shows the possible arrangement of the amino acids in PorACj in an α-helix. This means that this protein could form an amphipathic helix similar to the possible secondary structure in the monomeric PorH and PorA proteins [21,22,30]. In agreement with the experimental data (demanding a water filled pore with 1.4 nm diameter), the C. jeikeium channel is postulated to consist of oligomeric α-helical subunits. The number of subunits is an open question but this could influence channel conductance. Fig. 12A shows a possible arrangement of PorACj as an octamer seen perpendicular to the axis of the channel. Fig. 12B shows a side view of the octamer. The latter figure was created after 50 ns of unbiased molecular dynamics simulations. A fully stable conformation was not yet achieved at this stage and therefore the present structure suggestion is certainly preliminary (work in progress). Besides an octamer, it is also possible that the channel is formed by a hexamer, which would lead to a considerably smaller single-channel conductance, i.e. two maxima in the channel distribution as we found. We consider the possibility of an uneven number of monomers of PorACj in a channel as rather unlikely because the subunit of the PorA/H channel is presumably a PorA/PorH dimer. The present structure of the channel is definitely in contradiction to the 3D-structure of gram-negative bacterial porins [69] and that of the mycobacterial MspA channel [61] that both form β-barrel cylinders. On the other hand, it represents a similar structure as those of antibiotic channels, such as alamethicin [70], the cell wall porin PorB of C. glutamicum [71] and the ligand-gated ion channel in the inner membrane of Erwinia chrysanthemi (ELIC) [72].

This could mean that the PorCj monomer is orientated with the leucine, isoleucine and phenylalanine residues (Figure 12B, g d a) to the lipid phase, while glycine rich interfaces (c e) allow close contact to neighboring units. The four negative aspartates (D3, D28) and glutamates (E7, E31) together with the four lysines (K24, K27, K35, K40) are orientated to the channel lumen (f b e). At least one of the positive residues must take a dominant position in the otherwise charge-balanced protein causing the determined anion selectivity. The number of PorACj monomers in the homoooligomeric channel is not known yet and need further experimental and structural information about the channel. Five monomers are suggested to form the PorB channel of C. glutamicum [71] and the ligand-gated channel of prokaryotes [72]. Thus is very likely that the PorACj channel is formed by six to eight monomers because of its larger diameter.

Is PorACj of C. jeikeium the Subunit of the Ancestral Cell Wall Channel of Corynebacteria?

The many similarities between PorA/PorH and PorACj suggest that these channel-forming proteins form a family of proteins analogous to the MspABCD cell wall channel family of M. smegmatis and related species [58,73–75]. Even though PorACj structurally differs from the cell wall channel composition of the heterooligomeric channels within in the genus Corynebacterium there is a clear evidence for phylogenetic relationships of the investigated species. The different channel characteristics (e.g. diameter and selectivity) may indicate mirror adaptation to the wide-spread habitats of Corynebacterium species ranging from soil to skin and tissue of plants, animals as far as to man. In the first run mycolata were mainly classified according to properties of the phenotype and the chemical composition of their cell wall (containing meso-diaminopimelic acid, arabinose and glucose as major sugars [76]). Analysis of 16S rRNA provided deeper insight into separation of species within the monophyletic Corynebacteria-Mycobacteria-Nocardia-group although it cannot claim absolute classification accuracy [77–79]. Hence, strains yet known to be concomitant of porB and porA genes, namely C. glutamicum, C. efficiens, C. diphteriae, C. callutae and many others likely evolved from an ancestor of C. jeikeium [78]. A similar picture may also be derived from a phylogenetic tree of the PorA/H family of channel-forming proteins together with PorACj from the genus Corynebacterium shown in Figure 13. The distance between PorACj of C. jeikeium and PorA/H of many Corynebacterium species is similar. This could indeed mean that jbo2608 (porACj) of C. jeikeium could be related to the ancestor of the genes porH and porA that may have evolved by gene duplication. The interesting point in this relationship is that the PorA family of proteins is more closely related to PorACj than the PorH family (see Figure 13).
