Abstract

Background: To report on the technique and results of parallel endplate osteotomy (PEO) for severe rigid spinal deformity.

Methods: Between July 2016 and December 2018, 36 patients with severe rigid spinal deformities who underwent PEO were retrospectively reviewed after a minimum follow-up of 24 months.

Results: Following PEO, the kyphosis and scoliosis correction rates reached 77.4 ± 14% and 72.2 ± 18.2%, respectively. The median intraoperative estimated blood loss was 1500 mL and the operative time was 6.8 h. The SF-36 scores of physical function, role-physical, bodily pain, general health, vitality, social function, role-emotional and mental health changed from 62 ± 28, 51 ± 26, 49 ± 29, 35 ± 30, 53 ± 28, 45 ± 30, 32 ± 34 and 54 ± 28 at baseline to 81 ± 16, 66 ± 41, 72 ± 40, 64 ± 44, 75 ± 25, 71 ± 46, 66 ± 34 and 76 ± 28 at one year postoperatively, 82 ± 32, 67 ± 42, 81 ± 30, 71 ± 41, 80 ± 30, 74 ± 36, 68 ± 35 and 85 ± 33 at 18 months postoperatively, and 86 ± 21, 83 ± 33, 88 ± 26, 79 ± 39, 86 ± 36, 86 ± 48, 80 ± 47 and 91 ± 39 at 24 months postoperatively, respectively.

Conclusions: PEO is an effective technique for successful correction of spinal deformities. At the two year follow-up visit, all patients achieved better clinical results based on the SF-36 scores.

Background

Severe, rigid and angular severe kyphosis (Figure 1A, 1B, 1C, 1D, 1E and 1F) and kyphoscoliosis (Figure 1G, 1H, 1I and 1J) were considered to be insurmountable challenges for spinal correction surgery in the last century. Despite tremendous efforts by spine surgeons to find effective solutions, the corrective outcomes remain unsatisfactory, with a high incidence of neurological complications and massive bleeding, posing major threats to various spinal correction procedures and technologies.

In severe spinal deformities, the Cobb angle of the main curve is more than 80-100°; in rigid spinal deformities, the flexibility of the main curve is less than 10-30%[1]. Treatment is often accompanied by difficulties and complications. Many studies have identified a relationship between anterior thoracotomy and a further decline in patient pulmonary function; therefore, surgeons prefer a posterior approach alone[2-4].

Although different types of osteotomies have been described and widely used to address large, stiff scoliotic or kyphotic curves[5-11], it should be noted that abnormal pedicle development, including absence of pedicles, cause more difficulties in osteotomies. However, the International Scoliosis Research Society of America reported in 2011 that the incidence of complications including neural and non-neural injury during SPO, PSO and VCR was 28.1%, 39.1% and 61.1%, respectively[12-13]. To overcome these adversities, the present study was undertaken to evaluate and report on the technique and outcomes of parallel endplate osteotomy (PEO) for severe rigid spinal deformities at a single institution.

Methods

Patients

This retrospective study enrolled patients with severe rigid spinal deformities who underwent PEO between July 2016 and December 2018. Spinal deformities were diagnosed by human grid analysis, roentgenography after bending or traction, three dimensional (3D) computed tomography (CT) and 3D printing models. The inclusion criteria were 1) a spinal scoliosis and kyphosis angle more than 80°; 2) flexibility less than 25%; 3) receipt of one-stage posterior-only PEO and correction surgery; 4) a minimum 2-year postoperative follow-up. We excluded patients with spinal cord or nerve root injury or other serious respiratory complications before surgery.

The study protocol was approved by the institutional review board of the authors’ affiliated institution. Patient data were anonymized in the paper.
Assessment of deformity

Instrumentation levels were determined according to the Cobb angle and flexibility of the main curve. Severe rigid spinal deformities were defined as having curve angles more than 80°, with flexibility less than 25% by X-rays after bending or traction[14]. The site of osteotomy was usually chosen as the vertebra that contributed most to the deformity according to the apex of the deformity.

Surgical technique

All surgeries were performed as a single-stage procedure by a single surgeon (the corresponding author, SXD) through a posterior incision. The surgical procedure has been described in our previous paper[15].

The patient was placed in the prone position on the operating table, on chest rolls. A single midline posterior longitudinal incision was made to expose the area and previously determined levels. Paraspinal muscles and all soft tissues were stripped subperiosteally from the bone laterally to the tips of the transverse processes to allow the rigid spine to become more flexible. Then, the pleural and paravertebral vessels were bluntly dissected. An intraoperative radiograph with guide pins was obtained for accurate localization of the deformity and determination of the level and area for osteotomy. Pedicle screws were inserted in the cephalic and caudal aspects of the vertebrae identified for resection using a free-hand technique at all levels planned prior to surgery. It should be noted that abnormal pedicle development, including absence of pedicles, causes more difficulties in establishing the screw trajectory, and that screw insertion is time consuming[16]. Usually, the spine is stabilized with a short bent rod in situ adjacent to the resected area to avoid coronal and sagittal plane translation during the reduction maneuver. A complete laminectomy and facetectomy was performed to expose the spinal cord. In the thoracic spine, the rib heads were removed to allow complete resection of the lateral wall of the vertebral body and to allow untethered motion of the vertebral column. Usually, the spinal cord is located in the concave curve side, but sometimes slightly located in the convex curve side. If the spinal cord is located in the convex curve side, we need to be more careful to avoid causing neurological complications due to high tension of the spinal cord. For example, some patients have no dural sac in the spinal cord, and in other cases the spinal cord is as tight as a cord with the diameter of only one-third of a normal spinal cord. Any slight maneuver would make the action potentials decline sharply by over 50%, or even disappear. Timely identification and prompt intervention must be performed, including enlarging the resected area to reduce the abrupt turning tendency of the spinal cord.

The spinal nerves were carefully dissected and preserved, but if they obstructed the osteotomy, one level of spinal nerve roots of the thorax on the convex curve side was usually resected. For PEO, the pedicle of the vertebral arch, 4/5 of the posterior vertebra, the bilateral walls of the vertebra and the posterior wall of the vertebra (5 mm to endplate) (Figure 2A to 2D) were carefully removed using an osteotome, curette, rongeur and ultrasonic osteotome. The apex area of PEO was planned in which the anterior 1/5 of the vertebral body was preserved during osteotomy. Compression over the resected area and shortening of the spine were performed to reduce tension on the spinal cord (Figure 2E and 2F). The PEO area had two situations: 1) a single vertebral osteotomy, if the angle of the curve was less than 100° (Figure 3A to 3C), and 2) a multiple vertebral osteotomy, if the angle of the curve greater than 100° (Figure 3D to 3I).

The osteotomy was performed carefully to avoid over-penetration of the anterior vertebral body cortex or anterior intervertebral disc, for the purpose of providing a hinge point to avoid coronal and sagittal plane translation, and also to prevent injury to the major vessels in front of the vertebral body. Then, we inserted another pre-contoured correction rodon on the convex side to exchange the rods, 30° per correction. It was important in this step to keep an adequate compression force on the concave rod while its adjunct screws on the cephalic side were slightly released until the concave rod and screws were tightened one by one. In situ rod bending on the concave side should never be performed because it is very dangerous procedure to the naked spinal cord and applying too much torsion to the pedicle screws could easily cause screw loosening and rod bender to stick out and injure the spinal cord. Therefore, we did not use the bent bar in PEO. After repeated compression and shuttling the segmental transient rod, we finally placed the terminal fixation rods after the main correction was achieved. The temporary rods should be exchanged with new rods because their mechanical integrity may be impaired by the bend. Then, segmental derotation, compression, and distraction on the secondary curves were performed to achieve final correction. During the entire correction procedure, the dural
sac was closely observed to avoid migration in any direction, and tension of the spinal cord was assessed by observation and frequent palpation. Adequate and quick adjustments were needed to ensure that spinal cord tension does not exceed the initial state under distraction, and to prevent excessive kinking of the dural sac after spinal shortening. Kawahara et al. confirmed that the spine shortened within one-third of the height of the vertebrae would not lead to a functional change of the spinal cord\(^{17}\), but we did not worry about the excessive ruga of the dural sac. Spinal stability was always carefully maintained by the pedicle screw-rod system to prevent sudden migration of the spinal cord due to unstable instrumentation. We placed the terminal fixation rods after the main correction was achieved. After completion of resection and deformity correction, we filled any residual gap with resected vertebral body bone chips\(^{18}\).

We monitored somatosensory-evoked potential (SEP) and motor-evoked potential (MEP) to effectively monitor the spinal cord and nerve roots under the supervision of an experienced neurophysiologic physician throughout the PEO procedure, and an additional wake-up test was performed after finishing the correction step at the end of the surgery to ensure the neurological status.

**PEO grade**

Grade I: For patients with a scoliosis and kyphosis angle less than 80°, we recommend osteotomy with single vertebra by PEO (Figure 4A). The osteotomy angle can reach 50°-60°, and the correction rate can reach 80%-85% by the previous cases data. Grade II: For patients with a scoliosis and kyphosis angle between 80° and 100°, we recommend osteotomy with a single vertebra and the intervertebral disc by PEO (Figure 4B). The osteotomy angle can reach 70°-85°, and the correction rate can reach 70%-85%. Grade III: For patients with a scoliosis and kyphosis angle between 101° and 120°, we recommend osteotomy with two vertebrae and the intervertebral disc by PEO (Figure 4C). The osteotomy angle can reach 80°-100°, and the correction rate can reach 70%-75%. According to the severity of spinal cord folds, blood supply, tolerance of spinal cord twists, electrophysiological monitoring or wake-up experiments to determine whether to add the titanium mesh implants for the front support of the vertebral, we had a maximum spinal shortening of 5 centimeters (Figure 5A and 5B). For some patients with vertebral malformation, a more flexible osteotomy grade is adopted.

**Results**

In total, 36 severe rigid spinal deformities patients received a PEO. The 3D model provided accurate diagnostic and better surgical options. The kyphosis and scoliosis correction rates reached 77.4 ± 14% and 72.2 ± 18.2%, respectively. The median intraoperative estimated blood loss was 1500 mL and the operative time was 6.8 h (Table 1). The median duration of follow up was 32 months (range 24 to 50). Table 2 and 3 show SF-36 scores of the patients at baseline, one year, 18 months and 24 months postoperatively, respectively. The SF-36 scores of physical function, role-physical, bodily pain, general health, vitality, social function, role-emotional and mental health changed from 62 ± 28, 51 ± 26, 49 ± 29, 35 ± 30, 53 ± 28, 45 ± 30, 32 ± 34 and 54 ± 18 at baseline to 81 ± 16, 66 ± 41, 72 ± 40, 64 ± 44, 75 ± 25, 71 ± 46, 66 ± 34 and 76 ± 28 at one year postoperatively, 82 ± 32, 67 ± 42, 81 ± 30, 71 ± 41, 80 ± 30, 74 ± 36, 68 ± 35 and 85 ± 33 at 18 months postoperatively, and 86 ± 21, 83 ± 33, 88 ± 26, 79 ± 39, 86 ± 36, 86 ± 48, 80 ± 47 and 91 ± 39 at 24 months postoperatively, respectively (P < 0.05, Student's t test), indicating that the quality of life of the patients improved significantly after PEO.

However, although the clinical effect of the PEO technique was apparent, complications were unavoidable. L1 nerve root injury occurred in three (8%) patients, with abnormal SEP and MEP wave forms during the operation as shown by postoperative lower limb EMG. The symptoms of L1 nerve root injury were significantly improved by pharmacotherapy with mannitol and methylprednisolone and nutritional neurotherapy. Meanwhile, two (6%) cases developed hemopneumothorax, which was effectively repaired without any leakage, and a closed thoracic drainage tube was placed postoperatively. One (3%) patient experienced paralytic ileus which improved after gastric decompression, promoting intestinal motility and symptomatic medical treatment. One (3%) case developed superficial infection, which healed after thorough debridement. Two (6%) patients experienced distal screw loosening which improved after revision surgery. At the two-year follow up, we did not observe any other
complications, such as dural laceration, nonunion/rod breakage and adjacent segment kyphosis (Table 4). At the last follow-up, firm bony fusion was observed in all patients.

Data Analysis

Student's t test was used to evaluate the differences after surgery. Statistical significance was set at a value of P<0.05. Data are displayed as mean ± SD unless otherwise indicated.

Typical case

PEO grade II

A 38-year-old woman was diagnosed with idiopathic kyphoscoliosis (Patient No.11). Preoperative reconstructed CT scan and radiographs showed scoliosis (Cobb angle 63°) and kyphosis (Cobb angle 85°) (Figure 6A and 6B). Postoperative radiographs and reconstructed CT scan demonstrated the results of PEO with posterior spinal fusion. The scoliotic curve was corrected to 15° and the kyphotic curve to 25° (Figure 6C and Figure 6D).

PEO grade III

A 25-year-old woman was diagnosed with congenital kyphoscoliosis (Patient No.3). Preoperative reconstructed CT and radiographs showed scoliosis (Cobb angle 98°) and kyphosis (Cobb angle 112°) (Figure 6E and 6F). Postoperative radiographs and reconstructed CT revealed the results of PEO with posterior spinal fusion: the scoliotic curve was corrected to 18° and the kyphotic curve to 20° (Figure 6G and Figure 6H).

PEO grade IV

A 20-year-old woman with congenital kyphosis (Patient No.10). Preoperative photograph demonstrating reconstructed CT and radiographs showing Kyphosis Cobb (166°) planes (Figure 6I and 6J). Radiographs and reconstructed CT demonstrating the results of PEO with posterior spinal fusion and the titanium mesh implants for the front support of the vertebral, the kyphotic curve was corrected to 46° (Figure 6K and Figure 6L).

Discussion

Spinal deformity is a 3D deformity. Decompensation in the coronal and sagittal planes leads to specific complaints including pain, progression of deformity, deranged trunk balance, cardiopulmonary compromise, interference with daily living activities, and, in some cases, neurologic deficits. The surgical objective for severe (Cobb angle > 80°) kyphosis and rigid spinal kyphoscoliosis deformities is decompression of neurological elements and correction of the deformities, which have always been a great challenge for spine specialists. The surgical treatment is highly demanding and risky for both the surgeon and the patient. In severe rigid spinal deformities, conventional correction methods, including posterior instrumentation and fusion or combinations of anterior release and posterior instrumentation and fusion, are usually unsatisfactory. Therefore, a more aggressive approach is necessary.

Posterior osteotomies allow correction through a hinge action. For severe rigid spinal deformities, the resection of apical region of the deformity is often performed by the PVCR procedure. However, the hinge of the PVCR is the spinal cord, with the potential for various spinal cord-related neurological complications. PEO also differs from conventional vertebral column resection and PVCR in the usage of the spinal hinge, containing intraoperative deformity correction, and spinal reconstruction. However, the pedicle of the vertebral arch is taken as the main identification of most surgical osteotomies. As for severe rigid spinal deformities, osteotomy is just inside the pedicle, which limits the range of osteotomy and leaves the orthopaedic surgeon...
unsatisfied. Those osteotomies are mostly PSO, VCD, eggshell and so on. PEO, which has been described in our previously published paper\textsuperscript{[15]}, includes the pedicle of the vertebral arch, 4/5 of the posterior vertebra, the bilateral walls of the vertebra and the posterior wall of the vertebra (5 mm to the endplate), which does not require thorough pedicular osteotomy like PSO and resection of the intervertebral disc above and below the osteotomy site like VCR. Moreover, the endplate as a mark in PEO is easy to identify which has a large operating space, and is especially suitable for pedicle deformity or agenesis which is unrecognizable, which is easier to operate for orthopedic surgeons. With bone-bone fusion, we can achieve a higher spinal fusion rate and better spine stability in order to reduce the risk of rod breakage. For spine deformity, PSO and VCR are classic techniques and can achieve satisfactory results. Meanwhile, the PEO technique provides a new alternative treatment for spinal deformities, with an median intraoperative estimated blood loss was 1500 mL and the operative time was 6.8 h. The osteotomy angle can reach 110°-140°, basically satisfying any angle requirements for correction of spinal deformity. The kyphosis and scoliosis average correction rates reached 77.4% and 72.2%, respectively, which is better than the traditional correction rate of 55%-60%\textsuperscript{[25]}.

There is no permanent spinal cord injury in our series. Actually, the risk of spinal cord–related neurological complications is always emphasized in the literature concerning deformity correction. Potential neurological abnormalities should be noticed before corrective surgery. In our series of patients, 3/36 cases with very severe kyphoscoliosis had intraoperative neurological abnormalities. It was likely that the correction procedure caused spinal cord breakdown, thus increasing the tension on the spinal cord and reducing blood supply, accompanied by pathological changes. The patient presented with neurological symptoms intraoperatively, but operative exploration excluded mechanical compression, so the patient was treated with methylprednisolone and recovered completely within 2 weeks. Despite a different kind of anomaly, the corrective surgeries in these 3 patients achieved good results. We believe that a careful manipulation and continuous monitoring of spinal cord function are crucial to keep neurological function intact. In addition, severe deformity corrections that lead to spinal cord shortening can effectively relieve the over-tension of a tethered cord. The retrospective diagnosis of the patient was high risk spinal cord. Though there is no definitive evidence as to what caused the neurologic compromise, we believe that it might be related to the blood supply of the thoracic cord and preoperative functional status of the spinal cord, which tolerates little additional compromise. At the two year follow-up after surgery, it is obvious from the SF-36 scores that all patients achieved better clinical results and with no other complications.

**Conclusions**

We demonstrate that PEO is effective and relatively safe in correcting severe rigid spinal deformity. The PEO technique creates a hinge for spinal correction and spinal cord tension adjustment, and the correction can be performed under direct inspection and by observation and palpation of the tension in the spinal cord through the hinge. We propose the grade classification of PEO osteotomy, for the first time. At two year follow-up after surgery, it is obvious from the SF-36 scores that all patients achieved better clinical results.

** Declarations**

**Ethics approval and consent to participate**

The study protocol has been approved by the Clinical Research Ethics Committee of the Shenzhen University on May 10th, 2016 and has been registered. All the participants and also from parents or legal guardians of minor participants in the manuscript signed an written informed consent. All procedures were performed in accordance with relevant guidelines in the manuscript.

**Consent to publish**
Written consent was provided for images of the patients and techniques, clinical details and identifying information such as age, profession and gender to be included and published.

**Availability of data and materials**

All data generated or analysed during this study are included in this published article and its supplementary information files.

**Competing interests**

The authors declare that they have no competing interests.

**Funding**

The study was not supported by any funds.

**Authors’ contributions**

HL and SXD participated in drafting the manuscript, in designing the protocol and provides the original idea of the work. PX, participated in drafting the manuscript and in designing the protocol. GZZ participated in revising the manuscript critically and in designing statistical analysis. XDL participated in revising the manuscript critically with reference to the methods to evaluate variables. HGM and NDL, participated in revising the manuscript critically with reference to the treatment technics to be studied. All authors have read and approved the final manuscript and agreed to be accountable for all aspects of the work.

Table 4

Complications in the study patients

| Complication                  | Patients (n = 36) |
|-------------------------------|------------------|
| Dura laceration               | 0                |
| L1 nerve root injury          | 3                |
| Paralytic ileus               | 1                |
| Hemothorax                    | 2                |
| Superficial infection         | 1                |
| Nonunion/rod broken           | 0                |
| Distal screw loosening        | 2                |
| Adjacent segment kyphosis     | 0                |

Figures

Figure 1

Female, 22 years old, severe angular kyphosis. (A, B, C, D, E and F) Preoperative diagnosis was kyphosis: Cobb angle 166° by profile, X-ray after bending, three-dimensional CT. Female, 17 years old, (G, H, I and J) Preoperative diagnosis was kyphosis: Cobb 99° and scoliosis Cobb 97° by profile, X-ray after bending, three-dimensional CT.

Figure 2

Simple operation schema of the thoracic parallel endplate osteotomy (PEO) procedure. A, B and C: The resection region (the pedicle of the vertebral arch, 4/5 of the posterior vertebra, the bilateral walls of the vertebra and the posterior wall of the vertebra) is marked. D: The temporary stabilizing rod is placed to the concave side to complete spinal canal decompression and PEO is performed. E and F: Compression over the resected area and shortening of the spine are performed to reduce tension on the spinal cord. The surgeon then bends the rod in situ on the coronal plane or sagittal plane for correction and observes the migration of the dural sac; compression and bending of rods on both the convex and concave sides are undertaken to adjust tension of the spinal cord.
Figure 3

The 3-D digital demonstrations. A, B and C: A single vertebral PEO. D, E and F: The double-vertebra PEO. G, H and I: The three-vertebra PEO.
Figure 4

The PEO osteotomy grade classification. (A) Grade I: For scoliosis and kyphosis angle less than 80°, PEO with a single vertebra is recommended. (B) Grade II: For scoliosis and kyphosis (80°-100°), PEO with a single vertebra and the intervertebral disc is recommended. (C) Grade III: For scoliosis and kyphosis (101°-120°), PEO with two or more vertebrae and the intervertebral disc is recommended. (D) Grade IV: For scoliosis and kyphosis angle more than 120°, PEO with two or more vertebrae and the intervertebral disc is recommended. According to the severity of spinal cord folds, blood supply, tolerance of spinal cord twists, electrophysiological monitoring or wake-up experiments are used to determine whether to add titanium mesh implants for the front support of the vertebra.

Figure 5

(A) and (B) Spinal shortening during PEO.

Figure 6
A 38-year-old woman with idiopathic kyphoscoliosis who received grade II PEO. A and B: Preoperative reconstructed CT and radiographs showing scoliosis, Cobb (63°) and kyphosis, Cobb (85°). C and D: Radiographs and reconstructed CT demonstrating the results of PEO with posterior spinal fusion; the scoliotic curve was corrected to 15° and the kyphotic curve to 25°. A 25-year-old woman with congenital kyphoscoliosis who underwent grade III PEO. E and F: Preoperative reconstructed CT and radiographs showing scoliosis, Cobb (98°) and kyphosis, Cobb (112°). G and H: Radiographs and reconstructed CT demonstrating the results of PEO with posterior spinal fusion: the scoliotic curve was corrected to 18° and the kyphotic curve to 20°. A 20-year-old woman with congenital kyphosis who received grade IV PEO. I and J: Preoperative reconstructed CT and radiographs showing kyphosis Cobb, (166°). K and L: Radiographs and reconstructed CT demonstrating the results of PEO with posterior spinal fusion and the titanium mesh implants for the front support of the vertebra; the kyphotic curve was corrected to 46°.
