I. INTRODUCTION

It is difficult to overstate the scientific importance of understanding the origin of the highest energy cosmic rays. Ultra-high-energy cosmic rays (UHECRs) have been observed since the early 60’s [1] and a plethora of models have been proposed to explain their origin, including acceleration (bottom-up) processes in power astrophysical environments and (top-down) decay of super-heavy (GUT scale) particles [2].

In the late 90’s we proposed a model predicting that UHECR nuclei could be accelerated in the large-scale terminal shock of the superwinds that flow from the central region of starburst galaxies [3]. A few years later we also predicted that the highest energy cosmic ray nuclei will generate 20 to 30 degrees hot-spots around the starbursts, because of their magnetic deflection in the Galactic magnetic field [4].

Over the last decade, mounting evidence has been accumulating suggesting that the UHECR composition becomes dominated by nuclei at high-energy end of the spectrum [5][10]. Concurrently, the Pierre Auger Collaboration has provided a compelling indication for a possible correlation between the arrival directions of cosmic rays with energy $E \gtrsim 10^{18}$ GeV and a model based on a catalog of bright starburst galaxies [11][12]. The post-trial chance probability in an isotropic cosmic ray sky gives a Gaussian significance of $4.0 \sigma$. When data from the Telescope Array are included in the statistical analysis the correlation with starburst galaxies is stronger than the Auger-only result, with a post-trial significance of $4.7 \sigma$ [13]. In the best-fit model, $(12.1 \pm 4.5)\%$ of the UHECR flux originates from the starbursts and undergoes angular diffusion on a von Mises-Fisher scale $\psi \sim 15.1^{+6.6}_{-3.0}$ [1].

Together these observations lead to two critical questions:

1. What imprints may the evolution of starburst-driven superwinds leave in present-day observables?
2. To what extent can we decipher this archaeological record, exploiting information about the present-day universe in order to learn about or constrain the possible acceleration of UHECR nuclei in starburst-driven superwinds?

These are certainly very broad questions, and in this paper we attempt to take a first step towards answering these questions.

Before proceeding, we pause to note that median deflections of particles in the Galactic magnetic field are estimated to be

$$\theta_G \sim 3^\circ Z \left( E / 10^{11} \text{ GeV} \right),$$

where $Z$ is the charge of the UHECR in units of the proton charge $\psi$. Thus, the requirement $\theta_G \leq \psi$ implies that UHECRs contributing to the starburst anisotropy signal should have $Z \lesssim 10$ and $E/Z \sim 10^{10}$ GeV.

II. STARBURST ARCHEOLOGY

Starburst-driven superwinds are complex, multi-phase phenomena primarily powered by the momentum and energy injected by massive stars in the form of supernova (SN) explosions, stellar winds, and radiation [16]. According to the book, these superwinds are ubiquitous in galaxies where the star-formation rate per unit area exceeds $10^{-1} M_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$. This type of starbursting object, nicknamed far-IR galaxy ( FIRG), can be characterized by: (i) an IR luminosity, $L_{\text{IR}} \gtrsim 10^{14}$ erg s$^{-1}$, which is large relative to its optical luminosity $L_{\text{OPT}} \gg L_{\text{OPT}}$, and (ii) a “warm” IR spectrum (flux density at $60 \mu m > 50\%$ the flux density at $100 \mu m$).

The deposition of mechanical energy by supernovae and stellar winds results in a bubble filled with hot ($T \lesssim 10^5$ K) gas that is unbound by the gravitational potential because its temperature is greater than the local escape temperature. The
over-pressured bubble expands adiabatically, becomes supersonic at the edge of the starburst region, and eventually blows out of the disk into the halo forming a strong shock front on the contact surface with the cold gas in the halo.

Two distinct mechanisms have been proposed to explain the starburst anisotropy signal:

- UHECRs can be accelerated by bouncing back and forth across the superwind’s terminal shock (hereafter ARC model) [3].
- UHECR acceleration can occur in the disproportionally frequent extreme explosions that take place in the starburst nucleus due to the high star-formation activity [17]; e.g., low-luminosity gamma-ray bursts (ll-GRBs) [18].

A point worth noting at this juncture is that one would expect llGRB explosions to stochastically sample the locations of cosmic star-formation throughout the volume of the Universe in which they can be observed. Then the probability for a given type of galaxy to host a llGRB during some period of time would be proportional to its star-formation rate. Starburst galaxies represent about 1% of the fraction of galaxies containing star forming galaxies [19], and the probability of SN explosions is about one to two orders of magnitude larger in starbursts than in normal galaxies, e.g., the SN rate for M82 is about 0.2 – 0.3 yr$^{-1}$ [20] whereas for the Milky Way is $3.5 \pm 1.5$ century$^{-1}$ [21]. Note that these two effects tend to compensate each other, and so a straightforward calculation shows that UHECRs accelerated in llGRBs will have a stronger correlation with the nearby matter distribution than with starbursts [22].

Indeed, given the ubiquity of llGRB explosions we can ask ourselves why the correlation of UHECRs with starburst galaxies would be explained by the presence of this common phenomenon. Rather there must be some other inherently unique feature of starburst galaxies to account for this correlation. With this in mind, herein we focus on the ARC model [3]. In previous work [23, 24] we investigated the constraints imposed by the starburst anisotropy signal on the ARC model and we readjusted free parameters to remain consistent with the most recent astrophysical observations. We now investigate the minimum power requirement for UHECR acceleration at shocks.

The cosmic ray maximum energy for any multiplicative acceleration process is given by the Hillas criterion, which yields $E_{\text{max}} \sim Z \epsilon uBR$, where $R$ is the size and $B$ the magnetic field strength of the acceleration region, and $u$ is the speed of the scattering centers (i.e., the shock velocity) [25]. Now, the magnetic field $B$ carries with it an energy density $B^2/(2\mu_0)$, and the out-flowing plasma carries with it an energy flux $u B^2/(2\mu_0)$, where $\mu_0$ is the permeability of free space. This sets a constraint on the maximum magnetic power delivered through the shock [26]. Following [27], we combine the Hillas criterion with the constraint of the magnetic energy flux to arrive at the minimum power needed to accelerate a nucleus to a given rigidity $R$,

$$P_{\text{min}} = \frac{R^2}{2\mu_0 u} \sim 10^{44} \text{ erg s}^{-1} (\frac{u}{0.01 \text{ c}})^{-1} \left( \frac{R}{10^{10} \text{ GV}} \right)^2 .$$  \hspace{1cm} (2)
these powerful FIRGs could represent an early stage of the starburst evolution. The star formation history of Arp 220 is multiplex: in the central kpc, a 10 Myr old starburst provides the majority of the IR luminosity [32]. This is comparable to the mean age of the active starburst in M82, but somewhat younger than the stellar activity powering the central regions of NGC 253, see Appendix I. What’s more, data from supernova radio spectra of Arp 220 may be indicative of a very short, intense burst of star formation around 3 Myr ago [33], which could be the elephant in the room.

Now, the anisotropy correlation is observed to be spread over an angular region of size $\sim 20^\circ$. The spread originates in the scattering of UHECRs with magnetic fields as they propagate to the Earth. The scattering on magnetic fields also gives rise to a spread in the arrival times of UHECRs with respect to the IR emission. If all scattering takes place in the Milky Way the dispersion in the UHECR arrival times is roughly $10^3$ yr [34]. This seems a very short period of time to accommodate an order of magnitude change in $\mathcal{P}$. However, since the number density of gas in the halo region is $10^{-3} \leq n_{gh}/\text{cm}^3 \leq 10^{-2}$ [35,38] and the total pp cross section at $E \sim 10^{10}$ GeV is $\sigma_{pp} \sim 100$ mb, the characteristic time scale for pp collisions in the acceleration region is $1 \leq \tau_{pp}^{pp}/\text{Gyr} \leq 10$. For a nucleus of baryon number $A$ scattering off a proton, an order of magnitude estimate of the total cross section can be obtained from the empirical scaling $\sigma_{Ap} \sim A^{2/3} \sigma_{pp}$ [39]. Thereby, for a medium mass nucleus (carbon, nitrogen, or oxygen), the characteristic time scale to scatter off the gas in the acceleration region is $0.1 \leq \tau_{int}^{Ap}/\text{Gyr} \leq 1$. Moreover, the energy loss rate of baryon scattering is comparable to that of nucleon photodisintegration in the background radiation fields of the acceleration region, see Appendix II. All in all, this implies that even considering the upper range for estimates of the gas density in the halo, UHECRs ARC accelerated by the starburst supernwind could be stored in the acceleration region without suffering catastrophic spallations.

At last, we adopt the venerable leaky-box approximation to outline a first order model that can describe the dynamics of the starburst emission process. In analogy with the closed Galactic model of [40], we start with the assumption that, in a first stage, during the ARC acceleration process all cosmic rays remain confined to the galaxy by a suitable large magnetic field, even at the highest energies. In a second stage, the confinement power of the magnetic field (correlated with $L_{GR}$) gradually decreases and the UHECRs are trapped, but within reflecting boundaries surrounding the galaxy, such that at each encounter with the boundary, they have a time-dependent probability of escaping into the intergalactic space. This leakage of UHECRs is driven by diffusion with a time-dependent rigidity, but of course the larger the rigidity the less time spent in the confinement volume.

To develop some sense for the orders of magnitude involved, we recall that in each “scatter”, the diffusion coefficient describes an independent angular deviation of particle trajectories whose magnitude depends on the Larmor radius $r_L = 0.1Z^{-1} E_{10} B_{100}^{-1}$ kpc, where $E_{10} = E/10^{10}$ GeV and $B_{100} = B/100 \mu G$ [41,3]. That said, it is reasonable to assume that a medium mass nucleus with $E \leq 10^{10.7}$ GeV would remain trapped inside magnetic subdomains of size $\ell \sim 0.1$ kpc, attaining efficient diffusion when the wave number of the associated Alfvén wave is equal to the Larmor radius of the nucleus [42]. With a Kolmogorov form for the turbulent magnetic field power spectrum (with coherent directions on scales $\ell$), this gives for a diffusion coefficient

$$D(E) \sim 5 \ell_{0.1}^{2/3} B_{100}^{-1/3} E_{10}^{1/3} \text{kpc}^2/\text{Myr},$$

where $\ell_{0.1} = \ell/0.1$ kpc [43]. Neglecting a numerical constant of order one, the diffusion time to the “magnetic wall” is estimated to be $\tau_{diff}(E) \sim H^2/\langle D(E) \rangle$, where $H$ is the height of the halo [44]. For $H \sim 15$ kpc [45], the diffusion time is in the ballpark, $\tau_{diff}(E) \sim 50$ Myr$/E_{10}^{1/3}$. Note that a mean residence time in the confinement volume of $\tau_{res} \sim 0.1$ Gyr, would require cosmic rays to bounce once ($E \sim 10^{10}$ GeV) or two ($E \sim 10^{10.7}$ GeV) times in the reflecting boundaries. Therefore, for the problem at hand, the ratio of the diffusion coefficient in the wall to that in the confinement volume must not be unreasonably high. This is in sharp contrast to the classical leaky box description of Galactic cosmic rays [46].

Needless to say, the ad hoc assumption that the residence time of UHECRs is compatible with a single value is a rudimentary order of magnitude approximation, because particles originated in the center reside longer that those populating the halo periphery. A precise description of the storage/trapping mechanism, with a time-dependent probability of escaping into the intergalactic space, requires a numerical simulation that is beyond the scope of this paper. Besides, one may object our choice of fiducial values for $B$ and $H$, which could be considered somewhat off-center. Whichever point of view one may find more convincing, it seems most conservative at this point to depend on experiment (if possible) to resolve the issue. In the next section we examine a particular FIRG example that could provide a clear-cut experimental test of the ideas discussed above.

### III. NGC 891: THE SMOKING GUN

The Outer Limits spiral galaxy NGC 891 lives in the Local Super Cluster, some 9.7 Mpc away. The galaxy looks as the Milky Way would look like when viewed edge-on, and indeed the two galaxies are considered very similar in terms of luminosity and size [47]. However, HI observations reveal

---

2 The angular spread of a von Mises-Fisher distribution, the equivalent of a Gaussian on the sphere, corresponds to a top-hat scale $\Psi \sim 1.59 \times \psi$.

3 Our fiducial choice of $B$ is supported by full-blown simulations, which accurately capture the hydrodynamic mixing and dynamical interactions between the hot and cold phases in the out-flow [41]; for details, see [24].

4 NGC 891 appears in the end credits of the Outer Limits 1963 TV series.
structures on various scales. High resolution images of its dusty disk show unusual filament patterns extending into the halo of the galaxy, away from its galactic disk. The overall kinematics of the gas in the halo is characterized by differential rotation lagging with respect to that of the disk. The lag, which is more pronounced at small radii, increases with height from the plane. There is evidence that a significant fraction of the halo is due to a galactic fountain [49].

The slope of the luminosity function is powerful indicator of the main features of the host galaxy. On the one hand, if the star formation rate in the galaxy is constant, then the luminosity function describing the sources can be accommodated by a single unbroken power-law model. On the other hand, if the galaxy is starbursting then high-mass X-ray binaries would be formed, breaking the luminosity function slope. The break in the slope would decrease with time, and would be an indication of the time of previous bursts in the galaxy. The X-ray luminosity function of NGC 891 can be fitted by a single power-law, but with a slope typical of starburst galaxies and flux density ratio (at 60 µm/100 µm) corresponding more to normal spirals than starbursts [49]. Altogether this indicates that NGC 891 is a starburst in a quiescent state.

NGC 891, located in equatorial coordinates at (right ascension, declination) = (35.64°, 42.35°), is inside the ~20° angular window where the Telescope Array Collaboration reported an excess of events over expectations from isotropy [50]. More precisely, the hot-spot is centered at (19°, 35°), and has a local significance of 4σ down to E ~ 10^{10.1} GeV. More data are certainly needed to ascertain whether the hot spot originates in NGC 891. Should this be the case, it is clear that UHECR acceleration must have occurred in the past, when the galaxy was starbursting.

Note that, in very good approximation, UHECRs are emitted instantaneously by llGRB and they cannot remain unscathed inside the starburst core. Indeed, the production of very- and ultra-high energy neutrinos would be a clear indication that UHECRs are accelerated in the central region of the starburst [51]. In contrast, in the ARC model, the interaction of UHECRs with the gas and radiation fields in the halo is largely suppressed (for details, see Appendix III), and therefore the neutrino signal would be largely suppressed.

We stress once more that NGC 891 is a starburst in a quiescent state. Because of this, the production of UHECRs assuming typical starburst properties must have occurred in the past, when the starbursting nucleus was active. Now, since these cosmic rays cannot be stored in the nucleus, but only in the halo, we can conclude that the confirmation of NGC 891 as an UHECR source would disfavor acceleration through powerful explosions in the starburst nucleus, while providing some support for ARC acceleration with time-dependent reflecting boundaries surrounding the galaxy.

### IV. CONCLUSIONS

We have investigated whether starburst-driven superwinds satisfy the power requirements to accelerate UHECRs. Since the acceleration time scale is $O(10^7 \text{ yr})$, this quest by necessity has been fundamentally archaeological: we seek to exploit present-day observations in the interest of learning about the past. We have shown that NGC 891 provides fossil evidence that UHECRs may have been ARC accelerated in the past and remained stored in the acceleration region, where they diffused rather freely without suffering significant energy losses. When the confinement power of the magnetic field (correlated with $L_{\text{IR}}$) in the storage region started to gradually decrease a fraction of the cosmic rays began to escape at a rate that has slowly increased over time.

### Appendix I: Systematic Uncertainties

The estimate of the kinetic energy output for the starbursts is model dependent, and therefore subject to large systematic uncertainties. One source of uncertainty is the functional form relating $P$ and $L_{\text{IR}}$. A commonly-used, simplifying assumption when modeling the starburst histories is that the star formation proceeds continuously at a constant rate [53]. For a constant star formation rate (SFR), the Salpeter stellar initial mass function (IMF) [54] leads to ratios $P_{\text{today}}/L_{\text{IR,11}}$ and $M/L_{\text{IR,11}}$ which are a factor of ~3 smaller than the fiducial values given in (3) and (4). A factor of SFR_{11}/SFR_{10} ~ 1.5 comes from the adopted relation between SFR and $L_{\text{IR}}$ derived in [50] assuming that the mass spectrum between 10 and 100 $M_\odot$ follows a power-law with slope 2.35 [57]. IMFs which are considerably flatter than the Salpeter IMF lead to higher values of $P_{\text{today}}$ [58]. However, the point we want to make herein is not only that the uncertainty in the empirically determination of the proportionality constant relating $P$ and $L_{\text{IR}}$ is large, but also that for many purposes, a steady-state approximation of the starburst phenomenon is inadequate, and consequently the functional form relating $P$ and $L_{\text{IR}}$ must be time-dependent. In particular, there is evidence for more than one starbursting region in the nearby galaxy M82, with one of these star forming regions active until ~20 Myr ago, but suppressed over the last 10 to 15 Myr [59]. The mean age of the active starburst is $\lesssim$ 15 Myr [59]. NGC 253 has also a complex structure, with the possibility of two or more (a)synchronous starbursting episodes during its lifetime [61]. The central regions of NGC 253 contain a large population of rather young stars formed within the past ~30 Myr [62].

A second source of uncertainty steams from the shock velocity. Parameterized three-dimensional radiative hydrodynamical simulations that follow the emergence and dynamics of starburst’s superwinds seem to indicate that superwinds...
driven by energy-injection in a ring-like geometry can produce a fast (≥ 0.01c) transient flow along the minor axis [63].

Appendix II: Photodisintegration Time Scale

In this Appendix, we estimate the energy loss rate due to UHECR nucleus photodisintegration. We approximate the starburst core as a cylinder of radius ~ 200 pc and thickness ~ 80 pc. The spectral energy density for the radiation fields of M82 inside the core is shown in Fig. 1. It can be approximated by a broken power law,

\[ n(\varepsilon) = n_0 \begin{cases} (\varepsilon/\varepsilon_0)^\alpha & \varepsilon < \varepsilon_0 \\ (\varepsilon/\varepsilon_0)^\beta & \text{otherwise} \end{cases} \]

where \( \varepsilon \) is the photon energy, the maximum photon number density is at an energy of \( \varepsilon_0 = 11 \text{ meV} \), and where \( n_0 = 10^6 \text{ cm}^{-3} \text{ eV}^{-1} \), \( \alpha = 1.1 \), and \( \beta = -1.8 \) [52]. The spectrum is normalized so that the total number density of photons is \( \int n(\varepsilon) d\varepsilon \). Out in the halo, \( |z| \gtrsim 40 \text{ pc} \), for \( \varepsilon \gtrsim 10^{-3} \text{ eV} \), the photon density decreases with the square of the distance, i.e., \( n_0 = 10^6 \text{ cm}^{-3} \text{ eV}^{-1} (z/40 \text{ pc})^{-2} \). For \( \varepsilon \lesssim 10^{-3} \text{ eV} \), the spectral energy density is dominated by the contribution of the cosmic microwave background.

The photodisintegration time scale of a cosmic ray nucleus, with energy \( E = \gamma Am_p \) and Lorentz boost \( \gamma \), propagating through an isotropic photon background with energy \( \varepsilon \) and spectral energy density \( n(\varepsilon) \) is found to be

\[ \frac{1}{\tau_{\text{int}}} = \frac{c}{2} \int_0^\infty d\varepsilon n(\varepsilon) \frac{\sigma(\varepsilon')}{\gamma^2 \varepsilon^2} \int_0^{2\gamma \varepsilon} d\varepsilon' \sigma(\varepsilon') \]

where \( \sigma(\varepsilon') \) is the photodisintegration cross section by a photon of energy \( \varepsilon' \) in the rest frame of the nucleus, and where \( A \) is the nucleus baryon number and \( m_p \) the mass of the proton [65].

The photodisintegration cross section is approximated by a single pole in the narrow-width approximation,

\[ \sigma(\varepsilon') = \pi \sigma_{\text{res}} \frac{\Gamma_{\text{res}}}{2} \delta(\varepsilon' - \varepsilon_{\text{res}}) \]

where \( \sigma_{\text{res}} \approx 1.45 	imes 10^{-27} \text{ cm}^2 A \) is the resonance peak, \( \Gamma_{\text{res}} = 8 \text{ MeV} \) its width, and \( \varepsilon_{\text{res}} = 42.65A^{-0.21} (0.925A^{2.433}) \text{ MeV} \), for \( A > 4 \) (\( A \leq 4 \) the pole [66]). The factor of 1/2 is introduced to match the integral (i.e., total cross section) of the Breit-Wigner and the delta function [67].

Substitution of (6) into (7) leads to,

\[ \frac{1}{\tau_{\text{int}}(E)} \approx \frac{c \pi \sigma_{\text{res}} \varepsilon_{\text{res}}}{4 \gamma^2} \int_0^\infty d\varepsilon \frac{n(\varepsilon)}{\varepsilon^2} \Theta(2\gamma \varepsilon - \varepsilon_{\text{res}}) \]

where \( \tau_b \) is the photodisintegration time scale of medium mass (carbon, nitrogen, or oxygen) cosmic ray nucleus with \( E \gtrsim 4 \text{ GeV} \) has a Lorentz boost \( \Gamma \leq 10^4 \). A straightforward calculation shows that the photodisintegration time scale of medium mass (carbon, nitrogen, or oxygen) cosmic ray nucleus with \( E \gtrsim 10^{10} \text{ GeV} \) propagating in the photon background at \( z \gtrsim 1 \text{ kpc} \) is \( \tau_{\text{int}} \gtrsim 0.1 \text{ Gyr} \).

Note that for a medium mass nucleus, the energy loss per collision ~ \( \gamma m_p \) is negligible when compared to that of baryon scattering. Thus, the energy loss rate of hadronic collisions in the halo is comparable to that of photodisintegration.

In closing, we note that at the peak, the \( \Delta(1232) \) resonant cross section is roughly an order of magnitude smaller than the giant-dipole resonance; for \( \Delta(1600) \), these cross sections peak at 20 MeV and 300 MeV and are roughly 30 mb [69] and 3 mb [70], respectively. Besides, an oxygen nucleus of 1010.7 GeV has a Lorentz boost \( \gamma \sim 10^5 \) and so to excite the \( \Delta(1232) \) would require photons with \( \varepsilon \sim 0.1 \text{ eV} \). This is a decade of energy above the peak of the spectrum where the number of photons decreases by more than an order of magnitude, see Fig. 1. Altogether, the interaction time scale of photopion production is orders of magnitude larger than that of photodisintegration.

Appendix III: Assessing the Neutrino Flux

High-energy astrophysical neutrinos are the tell-tale signature of hadronic interactions. In this Appendix we examine whether the neutrino signal can be used to discriminate acceleration models which take place inside the starburst nuclei from those in which acceleration takes place out in the galactic halo.
Acceleration of UHECRs in the starburst nucleus has been proposed to originate in young neutron star winds [71, 72], tidal disruption events [34, 73], and IGRB explosions [18]. For relativistic winds of fast-spinning pulsars, the estimated neutrino flux produced while UHECRs cross the supernova ejecta surrounding the stars is within the IceCube reach [74, 75].

Independently of the acceleration mechanism, interactions of UHECR within the starburst nucleus could also lead to a measurable neutrino flux. The gas density in the starburst nucleus is related to the star formation rate and hence associated to the IR luminosity via the Kennicutt-Schmidt scaling [76], and is given by

$$n_{g,n} \sim 100 \left(\frac{L_{IR}}{L_{IR, MS2}}\right)^{0.715} \text{cm}^{-3},$$  

where, as noted in [51], the exponent of the correlation is in agreement with [77]. Taking the $\sigma_{\rho A}$ cross section introduced in Sec. [II] it is straightforward to see that the interaction time-scale for UHECRs to collide with the background gas is $O(10^4 \text{ yr})$. On the other hand, for the radiation background shown in Fig. [I] the photodisintegration time-scale in the starburst nucleus is $O(0.1 \text{ Myr})$.

In addition, the contribution of nucleus photodisintegration to the neutrino flux originates in the decay of the emitted neutron. Note that the maximum $\tilde{\nu}$ energy in the neutron rest frame is very nearly $Q_{\tilde{\nu}} \equiv m_n - m_p - m_e = 0.78 \text{ MeV}$, where $m_n$ and $m_p$ are the mass of the neutron and electron, respectively [73]. In the lab, the ratio of the maximum $\tilde{\nu}$ energy to the neutron energy is $Q_{\tilde{\nu}}/m_n \sim 10^{-3}$, and so the boosted $\tilde{\nu}$ has an average energy $E_{\tilde{\nu}} \sim 10^{-3}m_n$. This is in sharp contrast to baryon scattering, where the maximum neutrino energy could be about 0.1 that of the incoming cosmic ray [79]. Therefore, neutrino production is largely dominated by hadronic collisions on the gas environment of the starburst nucleus. An estimate of the expected diffuse neutrino flux from starbursts assuming UHECR interactions with the gas density given in [13] has been carried out in [51]. For a neutrino energy in the range $10^8 \leq E_{\tilde{\nu}}/GeV \leq 10^9$, the estimated single-flavor energy-squared weighted neutrino flux,

$$E_{\tilde{\nu}}^2 \Phi_{\tilde{\nu}} \sim 10^{-8.5} \text{ GeV cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1},$$

saturates the IceCube flux limit [80], and is therefore within reach of next generation experiments.

We have seen in Appendix II that out in the galactic halo, where UHECR accelerated in the starburst supernovae could be stored, the interaction time scale of photodisintegration and/or scattering off the gas is between 4 to 5 orders of magnitude larger than the one in the nucleus. Therefore, the associated neutrino flux would be largely suppressed. Indeed the expected neutrino flux would be below the cosmogenic neutrino flux and out of reach of next generation experiments; see Fig. 9 in [51].
