The development of ectoderm-derived appendages results in a large variety of highly specialized organs such as hair follicles, mammary glands, salivary glands, and teeth. Despite varying in number, shape, and function, all these ectodermal organs develop through continuous and reciprocal epithelial–mesenchymal interactions, sharing common morphological and molecular features especially during their embryonic development. Diseases such as ectodermal dysplasias can affect simultaneously these organs, suggesting that they may arise from common multipotent precursors residing in the embryonic ectoderm. During embryogenesis, these putative ectodermal stem cells may adopt different fates and consequently be able to generate a variety of tissue-specific stem cells, which are the sources for the various cell lineages that form the diverse organs. The specification of those common epithelial precursors, as well as their further lineage commitment to tissue-specific stem cells, might be controlled by specific signals. It has been well documented that Notch, Wnt, bone morphogenetic protein, and fibroblast growth factor signaling pathways regulate cell fate decisions during the various stages of ectodermal organ development. However, the in vivo spatial and temporal dynamics of these signaling pathways are not yet well understood. Improving the current knowledge on the mechanisms involved in stem cell fate determination during organogenesis and homeostasis of ectodermal organs is crucial to develop effective stem cell-based therapies in order to regenerate or replace pathological and damaged tissues.

### Development of Ectodermal Tissues and Their Appendages

During early embryogenesis, the ectoderm represents the external germ layer, which is composed of the surface ectoderm, neural crest, and neural tube. From the surface ectoderm the epidermis (i.e., skin) and other stratified epithelia (e.g., oral epithelium; Carlson, 2004) develop. Subsequently, these tissues give rise to diverse specialized structures (called ectodermal appendages) such as hair follicles, mammary glands, salivary glands, and teeth.

All ectodermal appendages develop through similar cellular mechanisms that involve an intimate and controlled crosstalk between the epithelium and mesenchyme, and share common morphological features during early organogenesis (Pispa and Thesleff, 2003). The first morphological sign of an appendage development is a thickening of the epithelium that forms the appendage placode. In most of the cases the placode invaginates into the mesenchyme and due to an important proliferation activity gives rise to a bud, while the surrounding mesenchyme starts to condense. The bud epithelium grows further into the adjacent mesenchyme and finally acquires an organ-specific configuration (Figure 1).

### Specification of Ectodermal Appendages: The Role of Epithelial–Mesenchymal Interactions

The precise mechanisms that define the specificity of the ectodermal appendages along the body are not yet well understood. Tissue recombination assays are valuable for investigating the role of the epithelium and mesenchyme in regulating the initiation and morphogenesis of ectoderm-derived organs.

Classical heterotopic tissue recombination experiments, in which epithelium and mesenchyme from different origin are re-associated, have demonstrated the importance of the mesenchyme for initiating the development, and establishing the pattern, of ectodermal organs (Kollar and Baird, 1969; Kratochwil, 1969; Sakakura et al., 1976; Sengel, 1990). The capacity of the mesenchyme to ectopically induce the formation of ectodermal organs has been shown in a large variety of experimental models. For instance, it has been demonstrated that the embryonic mammary mesenchyme has the ability to induce the formation of mammary buds in areas where mammary glands normally do not develop, such as in mid-ventral and dorsal epidermal regions (Cunha et al., 1995). Similarly, it has been established that embryonic dental mesenchyme is able to induce the formation of dental structures when combined with non-dental epithelia in vitro (Mina and Kollar, 1987). Likewise, *ex vivo* experiments have shown that the oral epithelium of birds is capable of forming tooth-like structures when in contact with mouse neural crest-derived mesenchyme (Mitsiadis et al., 2003, 2006). It is now broadly accepted that the mesenchyme regulates the morphogenetic events of the various ectodermal organs. However, it remains controversial whether the cytodifferentiation events occurring later in the epithelium are tissue-autonomous or strictly mesenchyme-dependent. For
example, the recombination of mammary epithelium with salivary gland mesenchyme gives rise to salivary glands (Figure 2) that secrete milk proteins instead of salivary proteins (Sakakura et al., 1976). In contrast to the previous findings, embryonic chick mesenchyme (dermis) has been shown to control the epithelial (epidermal) cell differentiation (Dhouailly et al., 1978): tarso-metatarsal scale-forming dermis instructs the dorsal epidermis to develop scales, while dorsal feather-forming dermis induces the formation of feathers in tarso-metatarsal epidermis. One possible explanation is that mammary epithelial cells may be committed to express tissue-specific proteins earlier than feather and scale epidermal cells. Along these lines, tissue recombination experiments can provide valuable information on the developmental stage in which tissue-specific stem cells are irreversibly committed. This has been elegantly demonstrated by heterochronal recombination assays using pituitary epithelium and salivary gland mesenchyme.
As mentioned above, skin and oral epithelia are derivatives from the embryonic surface ectoderm. Thus, during embryogenesis, a putative common stem cell population residing in the surface ectoderm would be determined to give rise to multipotent stem cells in skin and oral epithelia that would be further specialized to form ectodermal appendages (Figure 4). For instance, during mammalian embryogenesis, stem cells from the oral epithelium are committed to form a stratified oral mucosa, the highly specialized dental epithelium and salivary and pituitary gland epithelia, whereas stem cells from the skin ectoderm can give rise to epidermis, hair follicles as well as sebaceous, and mammary glands.

Most of the ectodermal organs undergo their terminal differentiation and become functional at postnatal stages. This holds true for salivary glands that complete their functional differentiation during postnatal stages. Similarly, mammary glands reach their major specialization during adulthood and notably during pregnancy. Finally, hair follicles fully develop and cycle only postnatally and teeth erupt after birth. However, the main morphogenetic processes during the development of ectodermal-derived organs occur during embryonic stages. During the morphogenetic stage, tissue-specific stem cells divide and give rise to more committed progenitors that will eventually differentiate into all the tissue-specific lineages (Figure 4).

In the hair follicle, eight different cell types originate from the epithelium. The cells directly responsible for the hair shaft (medulla, cortex, cuticle) formation; the IRS (Inner Root Sheath) lineages (cuticle, Huxley’s layer, Henle’s layer, and companion layer), which constitute the external support to the shaft; the outer root sheath (ORS) lineage, which separates the hair follicle-organ from the epidermis (Niemann and Watt, 2002).

In the adult mammary epithelium, two main cell lineages can be found: the contractile myoepithelial cells and the luminal cells that can be further subdivided into the ductal and the milk-producing alveolar lineages (Woodward et al., 2005).

The salivary gland is composed of acinar, ductal, and myoepithelial cells. Acinar cells can be subdivided into serous or mucous, depending on the composition of their secretion. Similarly, ductal cells can be grouped into three different lineages based on the duct type in which they reside, i.e., intercalated, striated, or granular ductal cells (Tucker, 2007).

Regarding the tooth, epithelium can give rise to outer enamel epithelium, stellate reticulum, stratum intermedium, and inner enamel epithelium (Figure 5) that eventually will differentiate into enamel-secreting ameloblasts (Mitsiadis and Graf, 2009). Lineage tracing experiments using lipophilic carboxyamine dyes, such as the fluorescent dye Dil, have contributed to the understanding of lineage commitment during odontogenesis (Figure 5). In order to identify putative multipotent stem cells in the epithelium of embryonic mouse molars, cells from different regions of the dental epithelium were labeled before the morphogenesis stage. At further stages, Dil dye is retained in the same area where it was injected, suggesting that the labeled cells were committed progenitors rather than multipotent stem cells (Mitsiadis et al., 2008). However, Dil labeling faces several limitations such as the dilution of the dye concentration after each cell division, and it cannot be ruled out the possibility of the existence of multipotent epithelial stem cells in the embryonic molars that were not targeted with Dil.

**LINEAGE COMMITMENT OF STEM CELLS DURING DEVELOPMENT OF ECTODERMAL ORGANS**

As mentioned above, skin and oral epithelia are derivatives from the embryonic surface ectoderm. Thus, during embryogenesis, a putative common stem cell population residing in the surface ectoderm would be determined to give rise to multipotent stem cells in skin and oral epithelia that would be further specialized to form ectodermal appendages (Figure 4). For instance, during mammalian embryogenesis, stem cells from the oral epithelium are committed to form a stratified oral mucosa, the highly specialized dental epithelium and salivary and pituitary gland epithelia, whereas stem cells from the skin ectoderm can give rise to epidermis, hair follicles as well as sebaceous, and mammary glands.

Most of the ectodermal organs undergo their terminal differentiation and become functional at postnatal stages. This holds true for salivary glands that complete their functional differentiation during postnatal stages. Similarly, mammary glands reach their major specialization during adulthood and notably during pregnancy. Finally, hair follicles fully develop and cycle only postnatally and teeth erupt after birth. However, the main morphogenetic processes during the development of ectodermal-derived organs occur during embryonic stages. During the morphogenetic stage, tissue-specific stem cells divide and give rise to more committed progenitors that will eventually differentiate into all the tissue-specific lineages (Figure 4).

In the hair follicle, eight different cell types originate from the epithelium. The cells directly responsible for the hair shaft (medulla, cortex, cuticle) formation; the IRS (Inner Root Sheath) lineages (cuticle, Huxley’s layer, Henle’s layer, and companion layer), which constitute the external support to the shaft; the outer root sheath (ORS) lineage, which separates the hair follicle-organ from the epidermis (Niemann and Watt, 2002).

In the adult mammary epithelium, two main cell lineages can be found: the contractile myoepithelial cells and the luminal cells that can be further subdivided into the ductal and the milk-producing alveolar lineages (Woodward et al., 2005).

The salivary gland is composed of acinar, ductal, and myoepithelial cells. Acinar cells can be subdivided into serous or mucous, depending on the composition of their secretion. Similarly, ductal cells can be grouped into three different lineages based on the duct type in which they reside, i.e., intercalated, striated, or granular ductal cells (Tucker, 2007).

Regarding the tooth, epithelium can give rise to outer enamel epithelium, stellate reticulum, stratum intermedium, and inner enamel epithelium (Figure 5) that eventually will differentiate into enamel-secreting ameloblasts (Mitsiadis and Graf, 2009). Lineage tracing experiments using lipophilic carboxyamine dyes, such as the fluorescent dye Dil, have contributed to the understanding of lineage commitment during odontogenesis (Figure 5). In order to identify putative multipotent stem cells in the epithelium of embryonic mouse molars, cells from different regions of the dental epithelium were labeled before the morphogenesis stage. At further stages, Dil dye is retained in the same area where it was injected, suggesting that the labeled cells were committed progenitors rather than multipotent stem cells (Mitsiadis et al., 2008). However, Dil labeling faces several limitations such as the dilution of the dye concentration after each cell division, and it cannot be ruled out the possibility of the existence of multipotent epithelial stem cells in the embryonic molars that were not targeted with Dil.

**ADULT EPITHELIAL STEM CELLS IN ECTODERMAL ORGANS**

There is increasing evidence for the existence of a pool of adult stem cells in several tissues that serves as a source for tissue...
Hierarchical model for stem cell commitment during development of various ectodermal organs. Skin and oral epithelia arise from the surface ectoderm. Putative multipotent stem cells residing in both epithelia can take different fate decisions, giving rise to diverse appendages. During further development of ectodermal organs, more committed tissue-specific stem cells arise from these putative multipotent stem cells in the skin and oral epithelium. Subsequently, tissue-specific stem cells give rise to progenitors or transient amplifying cells that differentiate into functional cell populations. Abbreviations: Alv, alveolar cell; Am, ameloblast; Com, companion layer; Cor, cortex; Csf, cuticle of the hair shaft; Csh, cuticle of the hair sheath; Duc, ductal cell; EcSCs, ectodermal stem cells; EpSCs, epithelial stem cells; Gr, granular duct cell; He, Henle’s inner root sheath layer; Hu, Huxley’s inner root sheath layer; Int, intercalated duct cell; Med, medulla; Myo, myoepithelial cell; MuA, mucous acinus; Oee, Outer enamel epithelium; ORS, outer root sheath; SeA, serous acinus; S1, stratum intermedium cell; Sr, stellate reticulum cell; Str, striated duct cell.

DiI labeling in dental epithelium. At the cap stage, the fate of cells from the dental epithelial bud is already determined. Four different, phenotypically distinct, cell compartments compose the enamel epithelium: outer enamel epithelium (oee); inner enamel epithelium (iee); stellate reticulum (sr); stratum intermedium (si). Two independent DiI labeling experiments (in green and red) traced the fate of cells from different regions in the dental bud epithelium. At a more advanced developmental stage (cap stage) the DiI dye is detected in the same compartments where it was previously injected.

Epithelial adult stem cells during development and homeostasis of ectodermal appendages

In a number of ectodermal organs, epithelial adult stem cells have already been identified. However, in the vast majority, the existence of an adult stem cell pool in the epithelium is suspected although it has not been yet well characterized. Fluorescence-activated cell sorting (FACS) has been widely used to separate the different cell populations residing in a tissue based on their differential expression of several cell surface proteins. Subsequently, their stemness can be assessed either in vitro or in vivo. In vitro, the ability of cells to self-renew and differentiate into multiple cell types is a hallmark of stem cells.
to form colonies or spheres containing various lineages has been used to define adult epithelial cells with stem/progenitor properties (Barrandon and Green, 1987; Dontu et al., 2003; Blanpain et al., 2004; Lombaert et al., 2008). Moreover, when disaggregated and replated as single cells, putative stem cells can form new colonies or spheres, showing self-renewal capacity (Barrandon and Green, 1987; Dontu et al., 2003). 

In vivo, transplantation assays have largely been used to prove that a given cell behaves as a stem cell in hair follicle (Blanpain et al., 2004), tooth (Ohazama et al., 2004a), mammary (Sleeman et al., 2006), and salivary glands (Lombaert et al., 2008). The previously mentioned transplantation into cleared mammary fat pads and the transplantation of dental cells under kidney capsules to prove their ability to develop tooth-like structures, are some examples. In salivary gland stem cell biology, ligation–deligation techniques forcing the putative adult stem cell expansion are used. Briefly, closing or ligating the main duct in a salivary gland causes wide organ damage and atrophy. The subsequent duct deligation, triggers a very intense process of gland regeneration which has been extensively studied to identify the putative adult stem cells (Scott et al., 1999; Carpenter et al., 2009).

Although very informative, most of these techniques do not reflect the physiological situation. Indeed, lineage tracing experiments using inducible Cre–lox technology have recently demonstrated that the potential of cells can be different during normal homeostasis and experimental conditions (van Keymeulen et al., 2011). Thus, there is a need to overcome such technical limitations in order to be able to unequivocally define epithelial adult stem cells in ectodermal appendages. Hereby, we provide an overview of the current knowledge on epithelial adult stem cells in some ectodermal appendages such as hair follicles, mammary glands, teeth, and salivary glands during normal development.

Similar to other rapidly renewing organs, quiescent, and active adult stem cells coexist in hair follicles (Li and Clevers, 2010). Cotsarelis and colleagues first proposed the presence of slow cycling and label retaining stem cells. Those cells are residing in the bulge, a small area close to the attachment-site of the erector pili (Cotsarelis et al., 1990). Bulge stem cells express the surface marker CD34 as well as a truncated isoform of Keratin 15, and they have the ability to form colonies in vitro and produce fully functional hair follicle and interfollicular epidermis in vivo (Trempus et al., 2003; Blanpain et al., 2004; Morris et al., 2004). Apart from the slow cycling bulge stem cells, actively proliferating stem cells have been also described. These stem cells express Leucine-rich G protein-coupled receptor 5 (Lgr5) and reside not only in the bulge but also in the hair germ. Lgr5-positive stem cells contribute to the renewal of the lower hair follicle components under physiological conditions, although they can be forced to regenerate the entire hair follicle, the sebaceous gland, and the interfollicular epithelium in transplantation assays (Jaks et al., 2008).

The existence of adult mammary stem cells (MaSCs) is strongly supported by the fact that any portion of the adult mouse mammary epithelium, at any developmental stage, is able to grow and give rise to an entire new ductal system when transplanted into epithelium-free fat pads (DeOme et al., 1959; Smith and Medina, 1988). However, the newly formed mammary epithelium can only be re-transplanted for approximately seven generations, suggesting that MaSCs have a finite life span (Daniel et al., 1968). Further attempts to characterize MaSCs using FACS revealed that Cd24lowCd49bhigh and Cd24lowCd29bhigh populations are enriched for MaSCs, based on their high regeneration ability when injected into cleared fat pads (Shackleton et al., 2006; Sleeman et al., 2006; Stingl et al., 2006). However, recent data based on lineage tracing experiments suggest that during postnatal mammary gland development, newly generated luminal or myoepithelial cells arise from unipotent progenitors rather than from multipotent adult stem cells (van Keymeulen et al., 2011).

Multiple lines of evidence support the existence of adult stem cells in salivary glands. Radiolabeling experiments have demonstrated the presence of multipotent cells in the intercalated ducts that can contribute to both acinar and ductal cell lineages (Zajicek et al., 1985; Man et al., 2001). More recently, Kishi et al. (2006) used a clonal assay to demonstrate the existence of common progenitors among neonatal rat submandibular gland cells. Damage-induced regeneration assays have served to isolate adult stem cell enriched populations from adult salivary glands based on their c-Kit expression (Lombaert et al., 2008). Moreover, Lombaert and colleagues isolated mouse submandibular gland cells from the duct area and cultured them in vitro in a sphere-forming assay. Thus, when c-Kit-positive cells were purified by FACS and transplanted into an irreversibly damaged mouse submandibular gland they were able to regenerate a functional gland, exhibiting stem cell properties.

Mouse incisors present a source of dental epithelial stem cells that allows them growing continuously throughout the animal’s life (Harada et al., 2002). These stem cells reside in the so-called cervical loop present in the labial side of the incisor. The differentiation process occurs along the epithelium from the labial side of the incisor starting from the cervical loop that constitutes the niche for such adult epithelial stem cells. Nevertheless, in mouse molars and human teeth, most of dental epithelium disappears shortly after tooth eruption. The only remaining epithelial cells are the epithelial cell rests of Mallassez (ERM), located in the periodontal ligament tissue. Although their function still remains unclear, sub-cultured ERM have the potential to differentiate into ameloblast-like cells, suggesting that they may be quiescent stem cells (Shinmura et al., 2008).

FLEXIBILITY OF ADULT STEM CELLS DURING REGENERATION

Adult stem cells have the capacity to give rise to all the tissue-specific progeny required during normal development and tissue homeostasis. However, epithelial adult stem cells retain some flexibility (or plasticity) that provides them the ability to contribute to the formation of different organs during regeneration processes triggered by wound repair or in the previously mentioned recombination assays. For instance, this plasticity has been observed in hair follicle adult stem cells during wound healing of epidermis. Stem cells from the bulge region of hair follicles contribute only to hair follicle progenies during both embryonic development and adult tissue homeostasis but they can also contribute to interfollicular epidermis during wound healing (Levy et al., 2005, 2007; Blanpain, 2010). Similarly, lineage tracing experiments in the mammary gland have recently demonstrated that although during normal postnatal development and homeostasis, cells arise only from committed progenitors, myoepithelial progenitors can be forced to be multipotent in mammary reconstitution assays.
in vitro, stem cells have the ability to give rise to pancreas and liver lineages. BMP antagonists, including Noggin, Chordin, Follistatin and related at the extracellular level by various molecules that function in inducing or inhibiting their expression. BMP signaling is regulated at the transcriptional level by various molecules that function as ligands for Notch1 receptor during tooth development. Thus, the plasticity of adult stem cells represents an advantage for the potential use of stem cell therapies in regenerative medicine. For instance, due to the lack of dental epithelium in erupted human teeth, obtaining functional enamel-producing ameloblasts from a non-dental source of stem cells constitutes a major challenge in the dental regeneration field. Hence, it has been shown that stem cells derived from other tissues such as bone marrow can contribute to the ameloblasts layer in the in vivo formed tooth after recombining them with dental and mesenchymal cells (Hu et al., 2006). Nevertheless, in this case, dental epithelial cells were still needed for an organized tooth reconstitution. Given their common origin, it is conceivable that adult stem cells from other ectodermal-derived tissues may be able to differentiate into dental epithelium. In fact, recombination of postnatal non-dental oral epithelium and embryonic dental mesenchyme gives rise to tooth-like structures demonstrating that, similar to hair follicle stem cells, adult oral epithelial stem cells retain a certain plasticity (Nakagawa et al., 2009). Further investigations to gain a better knowledge on the molecular and cellular mechanisms involved in ectodermal organs’ development and injury response are still required in order to successfully apply the regenerative therapies to human diseases and tissue damage.

**SIGNALING PATHWAYS INVOLVED IN THE REGULATION OF ECTODERMAL STEM CELLS**

Several signaling pathways coordinately regulate the initiation and further development of ectodermal organs. The study of transgenic animals has shed some light on which molecules regulate the processes of specification of the skin or oral ectodermal stem cells into diverse tissue-specific progenitors, as well as the consequent fate choices to give rise to the distinct cell populations that will build up the organ.

**BONE MORPHOGENETIC PROTEINS**

Bone morphogenetic proteins (BMPs) are secreted growth factors that belong to the transforming growth factor beta (TGFβ) superfamily (Zeng et al., 2010). They were first described by their ability to induce bone formation, but since then, they have been implicated in several processes such as proliferation, apoptosis, tumorigenesis, tissue repair, stem cell maintenance, and epithelial cell fate determination (Wagner et al., 2010). BMP signaling is activated when BMP ligand dimers bind to the receptor complex. Two different types of serine/threonine kinase receptors form the BMP receptor complex: BMP receptor type I (BMPRI) and type II (BMPRII). When the signaling is activated, BMPRII receptors phosphorylate BMPRI receptors, which in turn phosphorylate the cytoplasmic common mediator Smad (co-Smad or Smad4) inducing its binding to the receptor-activated Smads (R-Smads). Subsequently, the complex formed by the co-Smad and R-Smads is translocated to the nucleus where it binds to the BMP response elements (BRE) in the promoter of BMP target genes, inducing or inhibiting their expression. BMP signaling is regulated at the extracellular level by various molecules that function as BMP antagonists, including Noggin, Chordin, Follistatin and follistatin-related gene product (FLRG), Ventroptin, twisted gastrulation (Twsgh1), and the Dan/cerberus family of proteins (Zeng et al., 2010).

During early embryogenesis in vertebrates, BMP4 is considered to be the signal that induces the epidermal vs neural fate of the ectoderm at gastrulation stage (Wilson and Hemmati-Brivanlou, 1995). The levels of BMPs have shown to be important in the fate determination of later epidermal progenitors during embryogenesis. Thus, lowering the levels of BMP signaling by conditional overexpression of Noggin, a BMP antagonist, results in defects in ectodermal organs due to inappropriate fate inductions. For instance, K14-Noggin overexpressing mice show replacement of sweat glands by pilosebaceous units (Plikus et al., 2004) and conversion of the nipple to hair-bearing epithelia (Mayer et al., 2008). Similarly, the blockage of BmpRIB-mediated signaling in chicken embryos leads to the transformation of dorsal scales to feather filaments in the dorsal surface of the foot (Zou and Niswander, 1996). Expression of BMP4 in the early oral epithelium has been shown to be necessary for the induction of tooth formation (Ohazama et al., 2004), and Bmp7 deficient mice occasionally lack teeth (Zouvelou et al., 2009). Moreover, Cre-mediated loss of epithelial Bmpr1a results in striking defects in postnatal hair follicle differentiation, as well as in an early arrest of tooth morphogenesis at bud stage (Andl et al., 2004). Thus, BMP signaling plays an essential role in the organ-type specification and development initiation of different organs from ectodermal origin.

**NOTCH**

Notch signaling is a highly conserved pathway that involves cell-cell contact. In mammals, 4 receptors have been described (Notch1–Notch4) with 5 ligands (Jagged1, Jagged2, Delta-like1, Delta-like3, and Delta-like4). Upon ligand-receptor binding, the extracellular domain of Notch receptors is proteolytically cleaved. Subsequently, the intracellular domain (NICD) is translocated to the nucleus where it binds to the transcription factor CSL (CBF-1 in humans or RBP-J in mice), forming a complex that regulates the transcription of Notch target genes (Figure 6). Notch signaling has diverse and multiple functions on cell differentiation, proliferation, and survival.

The Notch pathway is a master regulator of cell fate determination. In invertebrates, Notch activation directs accurate cell fate choices by restricting differentiation toward alternative fates and permits the self-renewal and survival of multipotent cells (Artavanis-Tsakonas et al., 1999). In vertebrates, diverse cell types express the different Notch receptors and ligands, indicating that Notch signaling may have more complex functions (Figure 7). Notch signaling regulates the switch from basal to suprabasal fate in epidermis (Blanpain et al., 2006) and controls differentiation and homeostasis in hair follicles (Pan et al., 2004). In the mammary gland, Notch activation specifies the luminal cell fate (Yalcin-Ozuyusal et al., 2010). In the developing tooth, Notch signaling has been proposed as an important regulator of dental cell type specification in the enamel organ (Mitsiadis and Graf, 2009). Notch1 is expressed in stratum intermedium, whereas Jagged2 and Delta-like1 are expressed in the adjacent cell layer of inner enamel epithelium, suggesting that Jagged2 and Delta-like1 proteins may function as ligands for Notch1 receptor during tooth development.
FIGURE 6 | Schematic representation of the Notch signaling pathway.
The interaction between Notch receptor on one cell and its ligands on the
neighboring cell results in the proteolytic cleavage of Notch receptor and
release of its inter-cellular domain (NICD) into the cytoplasm. NICD
therefore translocates to the nucleus and interacts with cofactors to
regulate the expression of downstream genes.

(Wang et al., 2010). It is possible that cell fate
determination in developing dental epithelium occurs through
inhibitory interactions between adjacent epithelial cells. Notch
signaling seems to have an essential role in those interactions,
influenced by extrinsic signals belonging to other pathways such
as fibroblast growth factor (FGF) and BMP signaling pathways
(Wang and Graf, 2009; Mitsiadis et al., 2010).

WINGLESS-TYPE MMTV INTEGRATION SITE (Wnt)

Wnt ligands are secreted, cysteine-rich proteins that signal
through transmembrane receptors belonging to the Frizzled fam-
ily (Wodarz and Nusse, 1998). Wnt signaling can activate both
canonical and non-canonical pathways. The canonical transduc-
tion pathway involves the activation of the intracellular protein
Disheveled (Dsh). β-Catenin is consequently stabilized and
then translocated to the nucleus where it forms complexes
with TCF/LEF transcription factors regulating the expression of
target genes.

Wnt signaling has been implicated in the induction of placode
formation during early developmental stages of several ectoder-
mal organs (Andl et al., 2002; Chu et al., 2004). Hyper-activation
of canonical Wnt signaling in the mouse oral epithelium results
in the formation of supernumerary teeth due to a continuous
induction of dental epithelium thickening and subsequent tooth
development throughout life (Järvinen et al., 2006). Lef-1 is a Wnt
transcription factor that it is also involved in the transduc-
tion of canonical Wnt signaling. Deletion of Lef-1 in mice results
in the developmental arrest of ectodermal organs such as mam-
mary gland, hair, and tooth at the bud stage. Lef-1 overexpression
under the Keratin14 (K14) promoter in mice leads to an inappro-
priate positioning of hair follicles in the skin (Zhou et al., 1995).
Moreover, an ectopic formation of tooth-like structures and hair
follicles in lip furrow epithelium is apparent in these mice. Interest-
ingly, the expression of K14, and thus Lef-1, is higher in that region
than in the rest of the oral epithelium. Taken together, these data
suggest that Wnt signaling activation is necessary for the induction
of ectodermal appendages during normal development. Further-
more, its activation levels are crucial in regulating ectodermal stem
cell fate, forcing them to form appendages in ectopic sites when
altered.

FIBROBLAST GROWTH FACTORS

The FGF family is composed of 22 secreted polypeptides that bind
to specific transmembrane tyrosine kinase receptors. To date, four
different Fgfr genes have been described (Fgfr1–Fgfr4) encoding 7
different major proteins (FGFRs 1b, 1c, 2b, 2c, 3b, 3c, and 4) with
differing ligand-binding specificity (Itoh and Ornitz, 2011). FGFs
are among the main regulators of embryonic development con-
trolling cell proliferation, survival, and differentiation (Szebenyi
and Fallon, 1999).

The study of different mouse models in which FGF signaling
is altered has demonstrated their involvement in epithelial–mesenchymal interactions that characterize the development of
ectodermal organs. Abrogation of FGF signaling has been related
to skin alterations and a defective wound healing capacity (Werner et al., 1994; Ortega et al., 1998). Regarding skin appendages, a number of FGF mutants with hair defects exist (Hébert et al., 1994; Petiot et al., 2003). In addition, FGF8, FGF10, and FGF10/FGF2 signaling have been shown to be important during the early stages of mammary gland development (Maitreux et al., 2002; Eblaghi et al., 2004) pointing to FGFs as essential regulators of the specification of the ectodermal stem cells from the ventral skin to form mammary placodes during embryogenesis. FGFs have also been implicated in the development of oral ectoderm-derived organs such as salivary gland and tooth. In the salivary gland, FGF10 is crucial for the initiation and correct patterning of submandibular salivary gland (Ohuchi et al., 2000). During early odontogenesis, FGF signaling determines the position and patterning of teeth (Neubüser et al., 1997). Moreover, FGFs have been described as important regulators of dental epithelial stem cells. In the absence of FGF10, the putative stem cell niche termed cervical loop cannot be maintained and mouse incisors cease their growth (Harada et al., 2002). In conclusion, FGFs function as inducers of ectodermal appendage development and regulators of tissue-specific stem cells residing in the epithelium of different ectodermal-derived organs such as epidermis and teeth.

**ECTODYSPLASIN A (EDA)**

EDA is a member of the tumor necrosis factor (TNF) superfamily. Mice carrying mutations in Eda gene present defects in the development of several ectodermal organs such as hair, teeth, and sweat glands (Mikkola et al., 1999). Interestingly, mice overexpressing EDA in developing epidermis present supernumerary teeth and mammary glands. Furthermore, treating embryonic skin with recombinant EDA induces the formation of epithelial placodes (Mustonen et al., 2004).

**ECTODERMAL DYSPLASIAS**

Several types of tissue-specific diseases often affect ectoderm-derived organs. The existence of disorders affecting the development of more than one of these organs suggests that the function of a putative stem cell residing in the embryonic ectoderm may be altered. Ectodermal dysplasias are defined as a highly heterogeneous group of rare heritable disorders characterized by defects in two or more organs of ectodermal origin (Pinheiro and Freire-Maia, 1994). Dysregulation of genes involved in the normal ectodermal organogenesis can lead to ectodermal dysplasia. This is the case of the transcription factor p63, in which mutations in humans can be the cause of various ectodermal dysplasias (Vanbokhoven et al., 2011). Studies on p63 knockout mice have demonstrated that the p63 gene is crucial for the appropriate stratification of skin epidermis and the correct development of several ectodermal appendages (Mills et al., 1999; Yang et al., 1999). Furthermore, other mutations in molecules involved in the EDA signaling pathway cause severe pathologies in both humans and mice, such as hypohidrotic ectodermal dysplasia (Itin and Fistarol, 2004). Ectodermal dysplasias are often characterized by the absence of some ectodermal appendages from the embryonic stages. Thus, these disorders are likely the consequence of a failure during the process of stem cell specification that may be caused by either the loss of the potency or the self-renewal and proliferation capacity of early ectodermal stem cells.

**CONCLUDING REMARKS**

Ectoderm-derived skin and oral cavity, as well as the highly specialized appendages that arise from them, are in close contact with the environment. Consequently, these organs are exposed to a great risk of being damaged and it becomes extremely important that they retain regeneration capacity throughout the organisms’ life. Adult stem/progenitor cells represent the source for the repair of ectoderm-derived organs during tissue homeostasis as well as upon injury conditions. However, this source may be limited due to aging, or due to certain pathological conditions, leading to the inability of stem cells to repair the damaged tissue. Regenerative medicine tries to overcome these limitations.

Major efforts are being made to isolate and characterize putative adult stem cells in different ectodermal organs. However, in most of the cases, only stem cell enriched populations have been isolated, probably including not only putative stem cells but also more differentiated cell types. Several assays have been developed to assess the regeneration potential of putative stem cells in order to define their stemness. It is essential to bear in mind that those assays may not reflect the normal developmental process but instead they reproduce an injury-repair situation where stem cells may be forced to be more plastic. Thus, in situ lineage tracing experiments provide valuable information concerning cell fate determination under more physiological conditions.

Data obtained from the study of diverse knockout and transgenic mice have improved the knowledge on the regulation of stem cell fate determination at different developmental stages of ectodermal appendages. Signaling molecules belonging to different pathways have been shown to have important roles in such processes. Nevertheless, the tightly controlled interaction in time and space between these signaling pathways still remains unclear. Thus, a better understanding of the molecular mechanisms underlying cell fate choices during normal development and homeostasis of ectodermal-derived organs is mandatory in order to successfully make use of stem cell biology-based therapies in regenerative medicine.
