(Dated: December 23, 2008)

We present spectroscopic measurements of the Autler-Townes doublet and the sidebands of the Mollow triplet in a driven superconducting qubit. The ground to first excited state transition of the qubit is strongly pumped while the resulting dressed qubit spectrum is probed with a weak tone. The corresponding transitions are detected using dispersive read-out of the qubit coupled off-resonantly to a microwave line resonator. The observed frequencies of the Autler-Townes and Mollow spectral lines are in good agreement with a dispersive Jaynes-Cummings model taking into account higher excited qubit states and dispersive level shifts due to off-resonant drives.

When a two-level system is driven on resonance with a strong monochromatic field, the excited state population undergoes coherent Rabi oscillations. This coherent process is reflected in the appearance of two sidebands offset by the Rabi frequency from the main qubit transition in the spectrum. This leads to a three-peak fluorescence spectrum referred to as the Mollow triplet. When probing transitions into a third atomic level, two characteristic spectroscopic lines separated by the Rabi frequency appear, a feature which is called the Autler-Townes doublet. The Mollow triplet and the Autler-Townes doublet were observed for the first time in an atomic beam of sodium and in a He-Ne discharge laser, respectively. Later they have been measured in single molecules, single atoms and more recently also in quantum dots.

In quantum dots, molecules, single atoms and more recently also in quantum dots. Later they have been measured in single molecules, single atoms and more recently also in quantum dots.

- 233 MHz is the charging energy and $E_{\text{max}}/\hbar = 32.8$ GHz is the maximum Josephson energy. The transition frequency $\omega_{ge}$ can be controlled by an external magnetic flux $\Phi$ applied to the SQUID loop formed by the two Josephson junctions of the qubit. The transition frequency from the first $|e\rangle$ to the second excited state $|f\rangle$ is given by $\omega_{ef} = \omega_{ge} - \alpha$, where $\alpha \approx 2nE_C/\hbar$ is the qubit anharmonicity. The qubit is strongly coupled to a coplanar waveguide resonator with resonance frequency $\omega_r/2\pi = 6.439$ GHz and photon decay rate $\kappa/2\pi \approx 1.6$ MHz. A schematic circuit diagram of the setup is shown in Fig. 1(a).

When the ground to first excited state transition of the qubit is in resonance with the resonator ($\Delta_{ge} = \omega_{ge} - \omega_r = 0$), the strong coupling gives rise to the vacuum Rabi mode splitting from which we have determined a dipole coupling strength $g_{ge}/2\pi = 133$ MHz between the first two energy levels. In the non-resonant regime, where the qubit is far detuned from the resonator ($|\Delta_{ge}| \gg g_{ge}$), the system is described by the generalized Jaynes-Cummings Hamiltonian in the dispersive limit:

$$H_{JC} \approx \hbar \left[ \omega_r - \chi_{ge} |g\rangle\langle g| + \sum_{l=e,f,...} (\chi_{l-1,l} - \chi_{l,l+1}) |l\rangle\langle l| \right] a^\dagger a + \hbar \omega_g |g\rangle\langle g| + \hbar \sum_{l=e,f,...} (\omega_l + \chi_{l-1,l}) |l\rangle\langle l|. \quad (1)$$

In the first term, $\chi_{ge}$ and $(\chi_{l-1,l} - \chi_{l,l+1})$ describe both the qubit-state dependent resonator frequency shift and the ac-Stark shift of the qubit energy levels. The dispersive frequency shift $(\chi_{l-1,l} - \chi_{l,l+1})$ is determined by the coupling strength $g_{l,l+1}$ between the levels $|l\rangle$ and $|l+1\rangle$ mediated by the resonator field and the detuning frequency $\Delta_{l,l+1} = \omega_{l,l+1} - \omega_r$. $a (a^\dagger)$ are the annihilation (creation) operators of the single mode field. In the last term, $\chi_{l-1,l}$ describes the Lamb shift of the transmon levels due to the dispersive coupling of the qubit to vacuum fluctuations in the resonator.

We measure the Autler-Townes and the Mollow spectral lines according to the scheme shown in Fig. 1(b).
signal generators are used to apply the measurement ν to the 20 mK stage, the qubit is coupled capacitively through setup analogous to the one used in Ref. [19]. In the center at the transition the dressed states and the third qubit level (ν tone. Possible transitions induced by the probe tone between the dipole coupled dressed states with the coherent drive energy. Drive and probe transitions are indicated by black and red/blue arrows. The transmitted measurement signal is then amplified by an ultra-low noise amplifier at 1.5 K, down-converted onator by ∆/4 drive and probe tones ν. First, we tune the qubit to the frequency ωq ge/2π ≈ 4.811 GHz, where it is strongly detuned from the resonator by Δ/2π = 1.63 GHz. We then strongly drive the transition |g⟩ → |e⟩ with a first microwave tone of amplitude ε applied to the qubit at the fixed frequency ωd = 4.812 GHz. The drive field is described by the Hamiltonian \( H_d = \hbar \varepsilon (a^\dagger e^{-i\omega_d t} + ae^{i\omega_d t}) \) where the drive amplitude \( \varepsilon \) is given in units of a frequency. The qubit spectrum is then probed by sweeping a weak second microwave signal over a wide range of frequencies ωi, including ωge and ωef. Simultaneously, amplitude T and phase φ of a microwave signal applied to the resonator are measured [21]. We have adjusted the measurement frequency to the qubit state-dependent resonance of the resonator under qubit driving for every value of ε. Figures 2(a) and (b) show the measurement response T and φ for selected values of \( \varepsilon/2\pi > 65 \text{ MHz} \), two peaks emerge in amplitude from the single Lorentzian line at frequency ωge/f corresponding to the Autler-Townes doublet, see Fig. 2(a). The signal corresponding to the sidebands of the Mollow triplet is visible at high drive amplitudes \( \varepsilon/2\pi > 730 \text{ MHz} \) in phase, see Fig. 2(b). Black lines in Fig. 2 are fits of the data to Lorentzians. Peaks not fitted with Lorentzians correspond to the phase response of the Autler-Townes doublet.

An intuitive model explaining those two effects can be given in the dressed state picture [20]. In the situation where the drive is exactly on resonance with the qubit, the bare states |n, g⟩ and |n − 1, e⟩ of the uncoupled atom-field system are degenerate, where n is the average number of photons in the coherent drive. The dipole coupling splits the energy levels by the Rabi frequency \( \hbar \Omega_R \) and forms an energy ladder of doublets separated by the energy of the drive photons \( \hbar \omega_d \). The new dressed eigenstates dipole coupled to the field are symmetric and antisymmetric superpositions of the bare states |n, ±⟩ = |n, g⟩ ± |n − 1, e⟩, see Fig. 1(c). In the limit \( n \gg \sqrt{n} \), the allowed transitions between dressed state doublets appear at frequencies \( \omega_0 = \omega_{ge}, \omega_{g, −} = \omega_{ge} - \Omega_R \) and \( \omega_{−, e} = \omega_{ge} + \Omega_R \) which are the central line and the two sidebands of the Mollow triplet, respectively, indicated by black and red arrows in Fig. 1(c). The central line is not observed in our measurements as
the corresponding transition is completely saturated by the strong drive tone. Similarly, transitions from one pair of dressed levels $|n+1,\pm\rangle$ to the third level $|f\rangle$ at frequencies $\omega_{\pm,f} = \omega_{e,f} \mp \Omega_R/2$ correspond to the Autler-Townes doublet. The splitting of the dressed states is only well resolved, when $\Omega_R$ is considerably larger than the qubit linewidth.

The frequencies of the Autler-Townes doublet (blue data points) and of the Mollow triplet sidebands (red data points) extracted from the Lorentzian fits in Fig. 2(a) and (b) are plotted in Fig. 3. The splitting of the spectral lines in pairs separated by $\Omega_R$ and $2\Omega_R$, respectively, is observed for Rabi frequencies up to $\Omega_R/2\pi \approx 300$ MHz corresponding to about 6% of the qubit transition frequency $\omega_{ge}$.

In the simplest model, the continuous classical drive at frequency $\omega_d$ is expected to induce Rabi oscillations between the qubit levels $|l\rangle$ and $|l+1\rangle$ at the frequency $\Omega_{l,l+1}$

$$\Omega_{l,l+1} \approx \frac{2\varepsilon g_{l,l+1}}{\omega_d - \omega_{ge}}$$

depending linearly on the drive amplitude $\varepsilon$. Therefore, one would expect that the strong drive at the qubit transition frequency $\omega_d \approx \omega_{ge}$ should lead to a square-root dependence of the Autler-Townes and Mollow spectral lines on the drive power $P_d \propto \varepsilon^2$. However, the Autler-Townes spectral lines show a clear power dependent shift, see Fig. 3 and the splitting of both pairs of lines scales weaker than linearly with $\varepsilon$.

These effects can be fully understood calculating the different transition frequencies by numerically diagonalizing the Jaynes-Cummings Hamiltonian in the dispersive limit including the coherent drive on the qubit

$$H \approx H_{JC} + \sum_l \frac{\Omega_{l,l+1}}{2} (|l\rangle \langle l+1| e^{i\omega_d t} + h.c.).$$

Here we take into account only the drive terms between nearest neighbor energy levels since other transitions are strongly suppressed due to the near harmonicity of the transmon $^{25}$. This model is in good agreement with our data when considering the lowest 5 qubit levels, see solid black lines in Fig. 3. Because of the low anharmonicity $^{23}$ and large drive amplitude, many qubit levels must be included in the description. The calibration factor between the externally applied drive amplitude and $\varepsilon$ is the only free parameter in the fit.

Numerical diagonalization of Eq. (3) also leads to a qualitative understanding of the amplitude and phase information contained in the measurement signal. This is done by first calculating the pulled cavity frequencies using the pre-factor of $a^\dagger a$ in $H_{JC}$. Since the measurement rate is small $^{32}$, the measured signal is given by the averaged response of all the dressed-state pulled frequencies contained in the steady-state reached by the qubit under the strong drive tone. In the Autler-Townes configuration, the weak probe tone transfers a small population from the dressed ground and excited states to the dressed $f$ state, resulting in a change in the cavity frequency and a drop of transmitted signal. On the other hand, in the Mollow configuration, population is exchanged by the probe tone from the $g$ to the $e$ dressed-states. At low drive power, the dressed $g$ and $e$ states are equal superpositions of the bare $g$ and $e$ states such that no signal is measured. As the power is increased, these states get dressed in different proportion with $f$ and a signal is measured.

Finally, plotting the difference between the two Autler-Townes spectral lines (blue data points) and the sidebands of the Mollow spectrum (red data points) versus drive amplitude $\varepsilon$, the nonlinearity of the dressed state splitting becomes more apparent, see Fig. 4(a). The dashed line shows the linear dependence of the Rabi frequency Eq. (2) on the drive amplitude $\varepsilon$, which only fits to the data at low $\varepsilon$. The non-linear dependence at high $\varepsilon$, instead, agrees very well only with our full model, black solid line.

To confirm the direct relationship between the measured dressed state splitting frequency and the Rabi oscillation frequency of the excited state population we have also performed time resolved measurements of the Rabi frequency up to 100 MHz, see Fig. 4(c). The extracted Rabi frequencies (orange data points) are in good agreement with the spectroscopically measured Rabi frequencies (blue squares) over the range of accessible $\varepsilon$, as shown in Fig. 4(b).

In conclusion, we have observed the dressed state splitting of the strongly driven energy levels of a superconducting qubit. The frequencies of the Autler-Townes
FIG. 4: (a) Extracted splitting frequencies of the Mollow triplet sidebands (red dots) and the Autler-Townes doublet (blue dots) as a function of the drive field amplitude. Dashed lines: Rabi frequencies obtained with Eq. (2). Black solid lines: Rabi frequencies calculated by numerically diagonalizing the Hamiltonian Eq. (3) taking into account 5 transmon levels. (b) Zoom in of the region in the orange rectangle in (a). Orange dots: Rabi frequency \( \Omega_R \) vs. drive amplitude \( \varepsilon \) extracted from time resolved Rabi oscillation experiments, lines as in (a). (c) Rabi oscillation measurements between states \( |g\rangle \) and \( |e\rangle \) with \( \Omega_R/2\pi = 50 \text{ MHz and 85 MHz} \).

doublet and sidebands of the Mollow triplet determined using a dispersive measurement technique are in excellent agreement with theory. Splittings corresponding to Rabi frequencies of up to 300 MHz have been observed spectroscopically and are consistent with time resolved measurements. Dressed state splittings have also been suggested to realize tunable coupling between two qubits biased at their optimal points \[33\]. Our measurements are the first step towards the realization of this protocol.
